
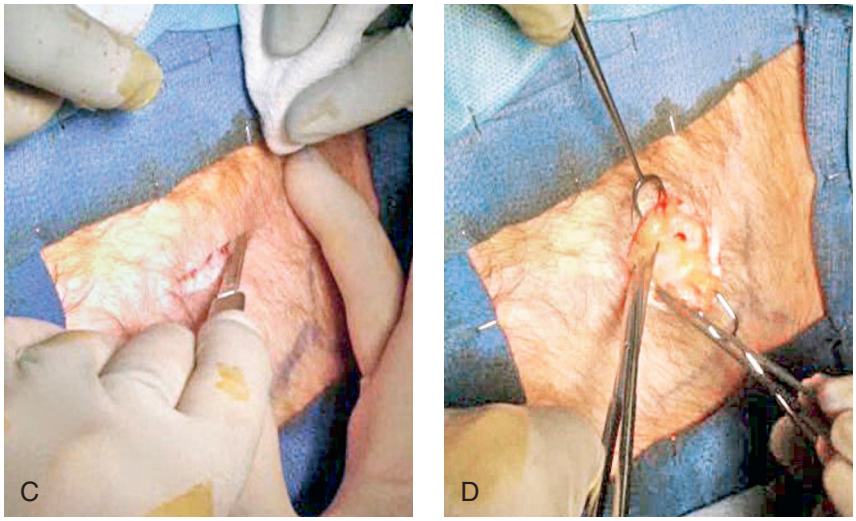
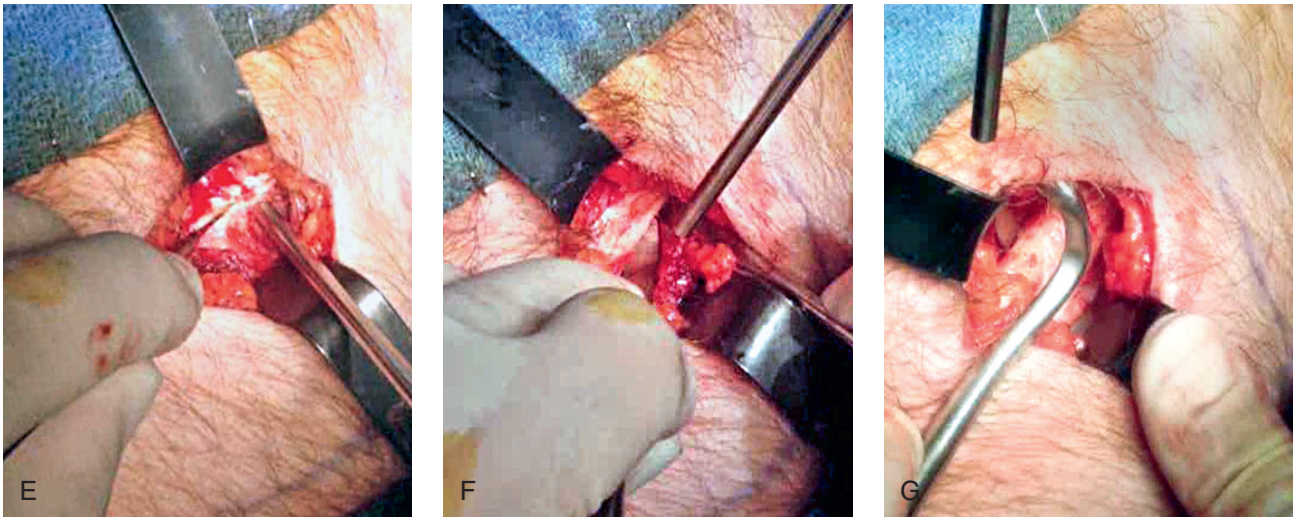
Incision marked | Local anesthesia injected



Skin incision | Scissors dissection down to cartilage



Perichondrium scored | Elevator used for subperichondrial dissection | Doyen used for subperichondrial dissection

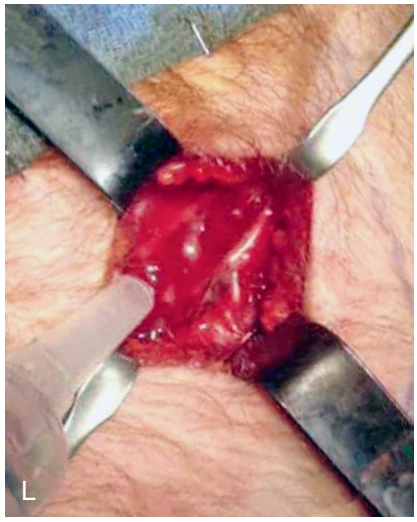
• **Figure 18-11** Intraoperative views of autogenous rib (cartilage only) donor site harvesting. **A,** The planned incision is marked directly over the rib cartilage to be harvested (≈4 cm incision length) before prepping and draping. **B,** Local anesthesia (Xylocaine 1% with epinephrine) is injected in the soft tissues below the skin and to the depth of the rib cartilage to be harvested. **C,** With a knife, the incision is carried through the skin and the subcutaneous tissue. **D,** Scissors dissection continues through the fascia directly over the rib cartilage. **E,** The perichondrium is scored with a knife directly over the mid portion of the long axis of the rib cartilage to be harvested. **F,** Curved and straight elevators are used to dissect in the subperichondrial plane circumferentially around the cartilage. **G,** A curved dissector (Doyen) is inserted underneath and around the rib cartilage. The Doyen is used to gain further exposure in the subperichondrial plane. *Continued*

Cutting proximal end of cartilage

Cutting distal end of cartilage

Cartilage graft

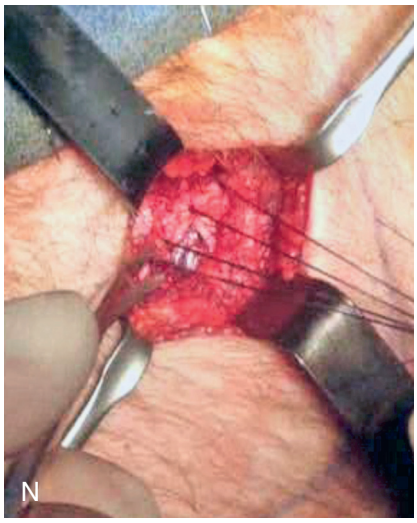
Defect checked for hemostasis



Water in wound prior to Valsalva maneuver

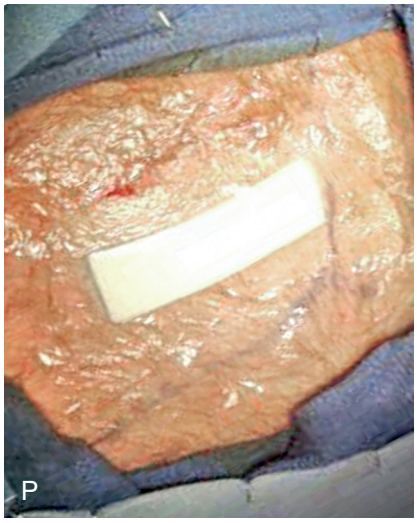
• **Figure 18-11, cont'd H,** A retractor is placed directly underneath the location for the full-thickness incision of the cartilage. A knife is then used to incise the full thickness of the cartilage on one end. **I,** A retractor is placed on the other end of the cartilage, and the knife is used to incise the cartilage. **J,** The cartilage graft is removed. **K,** After the removal of the cartilage graft, the defect is inspected for hemostasis. **L,** The wound is filled with saline, and the anesthesiologist introduces maximum end tidal volume and holds the area under pressure with the Valsalva maneuver. This confirms that no pneumothorax is present.

Perichondrial layer suture

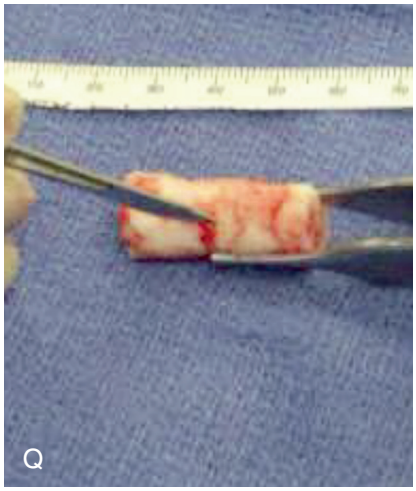


Fascia layer closure

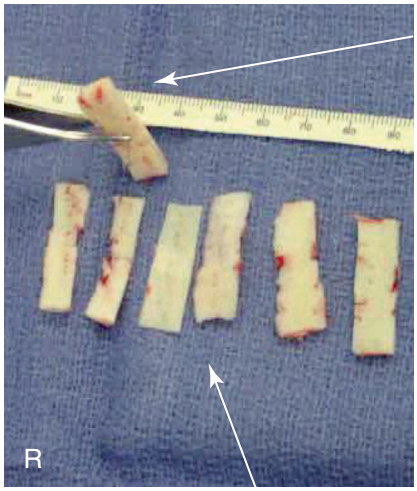
Skin closure



Occlusive dressing



Cartilage graft prior to crafting



Additional graft material crafted

• **Figure 18-11, cont'd M,** The perichondrial sleeve is approximated with interrupted suture ties (3-0 Vicryl). **N,** The deep and superficial fascia are closed with interrupted ties (3-0 Vicryl). **O,** Subdermal closure and then subcuticular closure are accomplished (5-0 Monocryl). **P,** Steri-Strips and an occlusive dressing (Tegaderm) are placed over the skin. **Q,** The harvested rib cartilage is crafted to suit the purposes of the recipient site. **R,** A crafted caudal strut graft can be seen. Additional grafts have also been crafted that can be used to reconstruct specific deficits (i.e., lower lateral cartilages, additional tip grafts, dorsal grafts).

- The perichondrial sleeve is approximated with interrupted suture ties (3-0 Vicryl).
- The deep and superficial fascia layers are closed with interrupted suture ties (3-0 Vicryl).
- Subdermal closure is with interrupted suture ties (4-0 Vicryl).
- The skin is closed with subcuticular running suture (5-0 resorbable).

Placement of Dressing

- The skin surface is cleaned with saline. It is then dried, and benzoin is applied.
- A limited number of Steri-Strips are placed directly over the closed wound.
- A small piece of cut gauze is placed directly over the Steri-Strips.
- An occlusive dressing (e.g., Tegaderm) is placed over the skin.

Postoperative Care

- The patient may shower without concern about moisture on the occlusive dressing that is covering the wound.
- The dressing remains intact for approximately 7 to 10 days.
- When the dressing is removed, no additional bandages are placed.

Alloplastic Grafts and Implants for the Augmentation of the Facial Skeleton

Porous Polyethylene Augmentation Implants

Specific patterns of skeletal dysmorphology may lead the individual to request and the surgeon to agree to augmentation and camouflage procedures for the sole purpose of enhancing facial aesthetics.[17,33,67,98,116,132,133,135,137] To avoid the need for graft harvesting and to limit concerns about the resorption of the graft over time, consideration of the use of alloplastic synthetic materials remains attractive. Alloplastic materials have been used to enhance and augment the facial skeleton over the years have included silicon, Biocoral, Biofax, Proplast, Teflon, Plasti-Pore, Seramic, polyamide-mesh, hydroxyapatite, Gore-Tex, methyl methacrylate, and porous polyethylene. These materials have been used with varying levels of success.[18,19,30,32,33,43-45,89,91,99,101,102,136] Their intrinsic biomedical properties generally fall short of ideal, but they may be adequate in specific clinical settings.

Of the currently available alloplastic synthetic implants that are commercially available, the materials that are seemingly most favorable for the augmentation of the facial skeleton are those made of porous polyethylene. Histologically, fibrous ingrowth into the polyethylene pores without capsule formation represents the key attribute of this particular material. The implants are placed in the subperiosteal plane and then preferably fixed in their new location to the underlying skeleton with titanium screws. Systemic antibiotics are administered perioperatively to limit the risk of infection. Technique-sensitive decisions regarding favorable sites for implant placement, preferred incision locations, extent of soft-tissue dissection, the size and shape of the implant selected, the crafting of the implant, the method of fixation, and postoperative wound management are all important factors for the limiting of morbidity and the achievement of desired results. Alloplastic implant extrusion, migration, infection, underlying bone resorption, and unsatisfactory aesthetic results all remain of concern.[142,140,141]

Augmenting the skeleton to camouflage facial dysmorphology with the use of porous polyethylene implants has been championed by Yaremchuk.[140-142] That author and others have demonstrated the effectiveness of this alloplastic graft approach for craniofacial reconstructive procedures and for purely facial aesthetic augmentation in specific clinical settings. The use of these implants in load-bearing locations as interpositional grafts or for purposes of nasal augmentation have consistently fallen short of the mark.

Conclusions

As part of maxillofacial surgery, grafting is a procedure that replaces missing structures with material from the patient's own body or with an artificial, synthetic, or natural substitute. When structures are deficient in the individual with a maxillofacial deformity, either additional bone or cartilage may be required. The grafting of interpositional defects or gaps of the mandible and maxilla is performed with autogenous bone, allogenic grafts, or alloplastic materials. The replacement of a condyle or an ascending ramus is generally done with autogenous costochondral graft, but vascularized fibular composite flaps and alloplastic joint replacements are additional options to consider. Nasal reconstruction is generally carried out with autogenous cartilage (e.g., septum, ear, rib) or, in some cases, autogenous bone. The use of alloplastic grafts for the augmentation of the facial skeleton is occasionally indicated. With adherence to basic biologic and aesthetic principles, an understanding of the individual's reconstructive and aesthetic needs, the development of a systematic treatment plan, and the maintenance of meticulous surgical technique, grafts can generally be used successfully to solve complex maxillofacial problems.

The surgical correction of the underdeveloped mandible was first reported in the American literature by Vilray P. Blair in the *Journal of the American Medical Association* in July 1909.[7] Dr. Blair presented two cases of retrognathia in which a horizontal ramus osteotomy was performed on each side of the mandible. The operative technique was carried out through a preauricular stab incision; an aneurysm needle was introduced posteriorly to the neck of the condyle and directed medially around to the ascending ramus, where it then exited through the cheek in front of the anterior border of the ramus. A Gigli saw was then put in place and blindly used to complete an osteotomy. The same procedure was completed on the opposite side of the jaw, and then the mandible was advanced into the desired occlusion. Intermaxillary fixation was applied until a callus formed. As a result of the limited bone contact across the osteotomy sites, a strong relapse tendency required persistent counterforces with continued intermaxillary elastics. Extrusion of the incisors with periodontal sequelae and recurrent malocclusion was a frequent observation.

Mandibular deficiency is the most prevalent form of dentofacial deformity.[2,30,32,39,43] It is more common among Caucasians than Africans or Asians, which suggests that a hereditary component is a predominant part of the etiology. During the mid 1970s, the public health service of the U.S. Department of Health, Education, and Welfare conducted an assessment of the occlusions of children who were 6 to 11 years old and 12 to 17 years old. These collected data indicated that approximately 20% of the sample populations had an Angle Class II malocclusion. Unfortunately, no other means of evaluation were performed to separate those children with a Class II jaw disharmony from those with a more straightforward dental Class II malocclusion. According to a National Health and Nutrition Examination Survey, severe mandibular deficiency (defined as >7 mm of positive overjet) in the U.S. Caucasian population has a prevalence of approximately 10%.[43] This pattern of Class II excess overjet is less frequent among African-American and Mexican-American groups. It can be assumed that more than 7 mm of overjet indicates a jaw discrepancy of such magnitude that orthognathic surgery would be the preferred way to manage the problem. The majority of these patients will have dentofacial deformities that fall into the categories of a long face growth pattern, maxillomandibular deficiency, or primary mandibular deficiency with or without arch-width discrepancy.

This chapter will focus on the patient with a *mandibular deficiency* who presents without a significant component of either vertical or horizontal upper jaw deformity. These individuals frequently will have a degree of maxillary

arch-width constriction that also requires correction. Although this categorization of primary mandibular deficiency may appear arbitrary, it focuses on a distinct subgroup of patients who routinely present for clinical assessment and treatment.

Functional Aspects

- Articulation errors during speech and swallowing difficulties that result from the Class II malocclusion are expected (see Chapter 8).
- Difficulties with chewing and with lateral and protrusive mandibular movements as a result of the Class II malocclusion are also expected.
- Upper airway obstruction during sleep often exists as a result of the retropositioned tongue. Obstructive sleep apnea should be ruled out (see Chapter 26).
- Detrimental long-term effects on the dentition and the periodontium as a result of the crowding of the mandibular teeth in limited alveolar housing or from previous camouflage orthodontic treatments are often seen (see Chapters 5 and 6).
- A higher incidence of temporomandibular disorders that result from mandibular deficiency Class II malocclusion have been reported (see Chapters 9 and 36).

Clinical Characteristics

- The lower lip is curled and everted, and it is often wedged behind the incisors with an accentuated labiomental fold. The shorter the lower anterior facial height, the greater the tendency for an accentuated labiomental fold.
- The gonial angles of the mandible tend to be relatively square. The shorter the face and the deeper the bite, the more acute the angles.
- There is a retruded and weak chin with a convex profile.
- There is a deficient mandible with the illusion of a large nose.
- There is a short chin-to-neck length and an obtuse angle, often with a double chin (even in a thin individual).
- The upper lip appears short, curled, and protrusive.

Dental Findings

- There are varied degrees of increased overjet with a Class II molar and canine relationship.
- The crowding of the teeth within the lower arch (i.e., the smaller the mandible, the greater the crowding) needs to be evaluated, and so does lower incisor flaring. Mandibular dental compensations often mask the true skeletal discrepancy.
- There are varied degrees of dental compensation in the upper jaw with either procumbency (i.e., "buck teeth") or maxillary incisors that are retroclined.
- The anterior deep bite (i.e., excessive overbite) may involve impingement of the anterior maxillary palatal tissues by the mandibular incisors.
- There is an excessive curve of Spee in the mandible (i.e., the deeper the anterior bite, the greater the excess curve).
- A reduced or negative curve of Spee is found in the maxillary arch.
- Dental crowding may also be seen in the maxilla (i.e., the more constricted the maxilla, the greater the crowding).
- Excessive wear facets, cusp fractures, and significant restorations in the posterior dentition are frequent findings in adults.
- Accelerated loss of the periodontium associated with the maxillary incisors (due to traumatic occlusion or previous orthodontics); the maxillary molars (due to arch constriction or previous orthodontics); and the mandibular incisors (due to supraeruption and anterior flaring from previous orthodontics) may be seen in adults.

Radiographic Findings

- Horizontal retrusion is measurable at the B-point of the mandible.
- The A-point–nasion–B-point angle is generally increased as a result of the retrusive lower jaw.
- Excessive procumbency of the mandibular incisors is frequently measurable.
- A vertically short and retrusive chin is generally measurable.
- The maxillary incisors are often procumbent, but they may be retropositioned as a result of previous extractions and camouflage orthodontics.

Treatment Indications and Objectives

The individual's immediate aesthetic concerns often center on 1) unfavorable lower-lip contours (e.g., a curled and everted lower lip with an accentuated labiomental fold) 2) a lack of prominence of the chin (e.g., a weak profile) and 3) an unattractive neck (e.g., a soft-tissue double-chin tendency).[27,38,39,42,48,47,50,59] Functional issues are also to be expected. For example, when the anterior bite is "deep," it will cause irritation of the gingival tissues of the palate just behind the maxillary incisors. Partial obstruction of the upper airway as a result of a retropositioned tongue is also common (i.e., heavy snoring, restless sleep, daytime fatigue, and documented or undiagnosed sleep apnea; see Chapter 26).[11,62] Complaints of an uncomfortable "dual" bite, chewing difficulties, masticatory muscle discomfort, and audible speech articulation errors are frequent. The individual with a Class II deep bite may have a greater tendency toward clicking (i.e., anterior disc displacement) in each temporomandibular joint.[25,51] Interestingly, there is little scientific evidence to support the notion that the signs of clicking will into more significant temporomandibular joint pathology (see Chapter 9).

When the mandible is deficient, with significant overjet, and when the anterior facial height is short, the lower lip tends to "get caught" behind the maxillary incisors. During growth, if the lower lip stays behind the upper teeth, then the upper teeth will adapt by tipping forward, thus creating a Class II, Division 1 malocclusion with varied degrees of maxillary incisor spacing. When the mandibular deficiency and the protrusive lower incisors are combined with procumbent maxillary incisors, the individual tends to be concerned with both the lack of chin prominence and the protruding maxillary anterior teeth (i.e., a toothy smile). Alternatively, if the lower lip remains in front of the maxillary incisors, there is an adaptive tendency for the maxillary incisors to tip lingually (i.e. Class II, Division 2).

The Role of Growth Modification in the Preadolescent Child

When the preadolescent child with mandibular deficiency is identified, a growth modification approach to treatment is frequently considered by the evaluating orthodontist.[13,33,32] Cozza and colleagues completed a systematic review of the literature to assess the efficacy of functional appliance use for enhancing mandibular growth in subjects with Class II malocclusions.[14] With the use of the Medline database, the survey covered the period from January 1966 to January 2005. A review of 704 articles confirmed only 22 that qualified for the final analysis. Of these 22 articles, only four randomized clinical trials were retrieved and found to be worthy of inclusion. *Interestingly, none of these four trials reported a clinically significant change in mandibular length to be induced by functional appliances in the patients with Class II deformities.* According to Proffit, the only concrete indications for the treatment of the preadolescent mixed dentition child with a mandibular deficiency who presents without an anterior open bite are the following[44]:

- Significant trauma to the palatal tissue (i.e., the lower incisors are injuring the palatal mucosa) or other indications of potential irreversible tissue damage
- Special concerns about the effects of the condition on the child's psychological well-being and the strong belief that the recommended treatment will alter this in a positive way
- Skeletal maturation that is well ahead of dental development so that the adolescent growth spurt occurs before the mixed dentition ends

Despite the review by Cozza and colleagues and Proffit's stated limited indications for early mixed dentition treatment in the child with a mandibular deficiency, a growth modification approach is often carried out by the evaluating orthodontist. The goals are frequently stated to be the restraining of forward maxillary growth while encouraging the mandible to grow downward and forward. In accordance with this rationale, mixed dentition growth modification treatment frequently incorporates the following steps:

1. *The alignment of the upper incisors* (i.e., the correction of lingual tipping with a Class II, Division 2 malocclusion) to prevent any interference with the forward movement of the mandible.
2. *Attempts to impede the biologic programmed forward growth of the maxilla and to facilitate the forward growth of the mandible.* Extraoral (posterior vectored) compressive forces are typically applied to the maxilla through a headgear device.
3. *Attempts to stimulate the mandibular posterior teeth to hypererupt while preventing the incisors from doing so.* During this process, it is hoped that the deep overbite will improve. An intra-oral functional appliance is often designed to facilitate these events.

Orthodontic Camouflage Approach

When the orthodontist proceeds with growth modification maneuvers and a less than favorable biologic response is realized, it is apparently tempting to proceed with a camouflage (dental compensation) approach (Figs. 19-1 through 19-5).[34,35,37,36,42] This would be carried out to "neutralize" the occlusion rather than to position the teeth solidly into the alveolar process in combination with orthognathic surgery. Current evidence-based medical standards recommend that the treating orthodontist have a "timeout" (i.e., a sit-down discussion and reassessment with the parents and the patient) that includes a review of the records (e.g., photos, models, radiographs) and a discussion of the biologic effects on the airway, the facial aesthetics, the occlusal stability, and the periodontium that may result from the various treatment options. A referral to an experienced orthognathic surgeon for the discussion of possible future surgical aspects is highly recommended.

An orthodontic camouflage approach for the individual with mandibular deficiency may take the form of maxillary premolar extractions so that the upper incisors can be retracted. This is generally combined with the flaring of the mandibular incisors. When this is carried out in the individual with a mandibular deficiency, the short-term objective of a neutralized occlusion may be achieved, but the following are potential sequelae: 1) unfavorable long-term facial aging 2) the risk for obstructive sleep apnea later in life 3) long-term periodontal deterioration 4) lower anterior crowding with recurrent malocclusion and 5) an inconsistent occlusion (i.e., a dual bite) (see Figs. 19-1 through 19-5). The orthodontist may feel favorable toward a camouflage approach on the basis of the belief that the patient can always have a "chin implant" to improve his or her facial aesthetics. Unfortunately, this approach will rarely achieve a pleasing aesthetic outcome. A chin implant tends to result in 1) an accentuated labiomental fold 2) an overly prominent pogonion and 3) a residual obtuse neck–jaw angle

• **Figure 19-1** A 20-year-old man with a primary mandibular deficiency growth pattern requested a surgical consultation for a weak chin. During his early teenage years, the patient underwent growth modification in an attempt to stimulate the forward projection of the mandible. This was followed by an orthodontic camouflage approach that included maxillary first bicuspid extractions to retract the anterior teeth. In addition, the mandibular anterior dentition was flared forward. His history was significant for heavy snoring, restless sleeping, and a degree of daytime fatigue, all of which are suggestive of obstructive sleep apnea. Examination confirmed a retrognathic mandible with a molar Class II deep-bite malocclusion. The mandibular incisors were crowded and procumbent. The family had hoped that a chin implant would be effective to manage the aesthetic effects. A sleep study was recommended, and an orthognathic approach with redo orthodontic treatment including lower bicuspid extractions was suggested as the preferred method to improve the airway, to achieve long-term dental health, and to enhance facial aesthetics. **A,** Frontal facial and occlusal views. **B,** Profile facial view and lateral cephalometric radiograph.

(Fig. 19-4). Furthermore, it does nothing for any baseline masticatory and airway dysfunction (see Chapter 37).

Definitive Reconstruction

Timing of Orthognathic Surgery

Stahl and colleagues carried out a longitudinal study to compare the biologic jaw growth changes of untreated subjects with Class II, Division 1 malocclusions as compared with those subjects with a normal Class I occlusion.[55] Each subject was followed from the prepubertal stage through the postpubertal stage of development. The study provides evidence of a similar growth pattern in both Class II and Class I subjects. The absolute amount of mandibular lengthening at the pubertal peak was significantly smaller in the Class II subjects than in those with normal occlusion. A significant deficiency was measured in overall mandibular length (i.e., Condyle-Gonion [Co-Gn]) in the Class II malocclusion subjects at the completion of growth. Interestingly, the

• **Figure 19-2** A 21-year-old woman with a primary mandibular deficiency growth pattern requested a surgical consultation for a weak chin. During her early teenage years, the patient underwent growth modification in an attempt to stimulate the forward projection of the mandible. This was followed by an orthodontic camouflage approach. The mandibular anterior dentition was flared forward. Her history was significant for restless sleeping and a degree of daytime fatigue, which are suggestive of obstructive sleep apnea. Examination confirmed a retrognathic mandible with a Class II malocclusion. The mandibular incisors were crowded and procumbent. The family had hoped that a chin implant would be effective to manage the aesthetic effects. A sleep study confirmed obstructive sleep apnea (respiratory disturbance index = 18/hour). An orthognathic approach with redo orthodontic treatment including lower bicuspid extractions was recommended as the preferred method to improve the airway, to achieve long-term dental health, and to enhance facial aesthetics. **A,** Frontal facial and occlusal views. **B,** Profile facial view and lateral cephalometric radiograph.

authors' findings show that a Class II dentofacial disharmony does not have a tendency to self-correct with growth.

There are numerous reports in the literature of surgeons carrying out successful orthognathic corrections in patients with mandibular deficiencies who are between the ages of 13 and 15 years. This is before the age at which growth maturity is typically considered to be complete. Interestingly, after the patient with a mandibular deficiency has undergone successful surgical correction, there are no reports late mandibular catch up growth.[5,20,23,29,45,52,61]

A review of available research data and clinical reports indicated that, when orthognathic surgery was undertaken in the patient with a mandibular deficiency as early as the completion of the adolescent growth spurt, further significant forward growth of the mandible almost never occurred.[31,55] Further horizontal growth of the maxilla at this age is also not expected. In theory, limited vertical growth of both the mandible and maxilla may continue; however, if it does, it tends to be proportionate. Proceeding with definitive orthognathic surgery in the patient with a

• **Figure 19-3** A 20-year-old man with a primary mandibular deficiency growth pattern requested a surgical consultation for a weak chin. During his the early teenage years, the patient underwent growth modification in an attempt to stimulate the forward projection of the mandible. This was followed by an orthodontic camouflage approach. The mandibular anterior dentition was flared forward. The patient's history was significant for heavy snoring, restless sleeping, and a degree of daytime fatigue, all of which are suggestive of obstructive sleep apnea. Examination confirmed a retrognathic mandible with clockwise rotation of the maxillomandibular complex. The mandibular incisors were crowded and procumbent. He had hoped that a chin implant would be effective to manage the aesthetic effects. An orthognathic approach with redo orthodontic treatment including lower bicuspid extractions was recommended as the preferred method to improve the airway, to achieve long-term dental health, and to enhance facial aesthetics. **A,** Frontal facial and occlusal views. **B,** Profile facial view and lateral cephalometric radiograph.

mandibular deficiency as early as the age of 13 or 14 years—but only after the eruption and orthodontic alignment of the teeth—is generally safe from a growth perspective.

Periodontal Considerations before Orthodontic Treatment

The position of the mandibular incisors in the alveolar housing has important periodontal consequences (see Chapter 6). In the retrognathic patient, the more the mandibular incisors are orthodontically tipped forward, the greater the chance of labial bone loss and gingival recession. There should be a healthy band of attached gingiva at the beginning of treatment and flaring of the incisors is to be avoided. This is a frequent concern in borderline crowding cases, when the final decision is made to not extract and then further labial tipping of the incisors occurs.

Even after successful gingival grafting, if further incisor flaring is allowed to occur in the presence of deficient labial bone, negative periodontal sequelae are to be expected. For patients with borderline crowding, if the incisor crowns are

• **Figure 19-4** A 29-year-old women arrived to discuss chin aesthetics. During the mixed dentition, she was recognized as having mandibular deficiency and a constricted maxillary arch width. At that time, she underwent growth modification techniques that included headgear. She also underwent rapid palatal expansion followed by compensatory orthodontic mechanics to neutralize the occlusion, but this also involved proclination of the incisors. A retrusive profile and a dual bite remained. The patient had recently undergone the placement of a chin implant without fixation. Aesthetic modification of the anterior maxillary dentition was also completed. The patient was displeased with the cosmetic results of a deepened labiomental fold, a mobile chin implant, and a "button" appearance during lip closure. There is a dual bite with Class II malocclusion when the teeth are in centric relation. **A,** Oblique and frontal facial views. **B,** Profile facial view and lateral cephalometric radiograph 6 months after chin implant placement.

morphologically large, the judicious use of interproximal reduction may create the needed space to uncrowd the arch and to simultaneously upright the teeth (see Chapter 17).

Orthodontic Preparation for Orthognathic Surgery

The clinicians (i.e., the orthodontist and surgeon), the patient, and the patient's family should agree about the treatment approach from the outset. It makes no sense for the orthodontist to tell the patient that he or she will first try to avoid surgery. The orthodontic objectives are diametrically opposite, depending on plans for either full correction (i.e., surgery and orthodontics) or camouflage (i.e., orthodontics alone). When a definitive correction is planned for the individual with mandibular deficiency, lower extractions to uncrowd the arch should always be considered. The need for maxillary extractions is not typical. The labial

• **Figure 19-5** A 43-year-old woman arrived to discuss the aesthetics of her weak chin and premature facial aging. During her late mixed dentition, she was recognized as having mandibular deficiency with a Class II malocclusion. At that time, she underwent growth modification techniques followed by compensatory orthodontic mechanics. This included upper first bicuspid extractions, the retraction of the anterior maxillary teeth, and the proclination of the mandibular incisors, all in an attempt to neutralize the occlusion. A retrusive profile and a dual bite remained. The weak profile of her adolescence had progressed into premature facial aging. She also had a lifelong history of obstructed nasal breathing, restless sleeping, and excessive daytime fatigue, all of which are suggestive of obstructive sleep apnea. An orthognathic approach with redo orthodontic treatment including lower bicuspid extractions was recommended as the preferred method to improve the airway, to achieve long-term dental health, and to enhance facial aesthetics. **A,** Frontal facial and occlusal views. **B,** Profile facial view and lateral cephalometric radiograph.

region of the mandibular incisors should be assessed for the need for gingival augmentation before the initiation of treatment.

For the patient with mandibular deficiency who has agreed to a combined treatment approach, an important orthodontic objective is to place the incisors more completely within the alveolus. Incisor placement will determine the eventual horizontal and vertical positioning of the mandible in relation to the maxilla as well as the long-term periodontal health.

The orthodontic leveling of an excessive curve of Spee in the lower arch is accomplished through a combination of the intrusion of the incisors and the extrusion of the mid-arch posterior teeth. With an excessive curve of Spee, premolar extrusion gives the major effect with only a small amount of incisor intrusion to be expected. This is initiated before surgery, but it is most efficiently fully accomplished after the mandible has been surgically repositioned (i.e., forward and down). Alternatively, if extensive intrusion of the anterior teeth is desired to correct the deep curve, this

should be done before the mandibular advancement surgery. The correction of a deep curve of Spee via incisor intrusion will result in less clockwise rotation of the mandible in association with surgical advancement. This can be leveraged for enhanced profile aesthetics.

The mechanics of the orthodontic leveling of the curve of Spee will generally result in the lengthening of the arch. The arch expansion primarily occurs at the incisors (i.e., labial flaring) and, to a lesser degree, at the molars. Space is required for both leveling and for aligning. For this reason, pre-alignment extractions to create space will be required if the severity of the curve of Spee is significant and if the available alveolar bone is limited. With a combination of incisor crowding and a deep curve of Spee, extraction therapy is always preferred. If the upper incisors are extremely flared, maxillary premolar extraction to gain space for retraction is also preferred; however, this is rarely the case.

When the deficient mandible is surgically advanced and vertically lengthened to achieve a more ideal overbite and overjet, the relative widening of the mandibular arch in the molar region occurs. Maxillary arch expansion may then be required to correct posterior crossbites. If more than several millimeters is required, then simultaneous surgical arch expansion of the maxilla through segmental Le Fort I osteotomy is the preferred approach (see Chapter 17).

Key aspects of presurgical orthodontics in the individual with mandibular deficiency include the following:

- Recognizing the need for extractions in the mandible and incorporating this information into the treatment plan from the beginning
- Recognizing the need for the surgical expansion of the upper arch (consider incorporating Le Fort I segmental osteotomies to widen the arch into the treatment plan from the beginning; see Chapter 17)
- Aligning the teeth independently within each arch with the objective of a compatible postsurgical occlusion
- Establishing the preferred sagittal and vertical positions of the incisors in the alveolar bone so that the jaw reconstruction that follows will result in enhanced facial aesthetics and improved head and neck function.

Additional orthodontic considerations for the individual with mandibular deficiency include the following:

- To manage an excessive curve of Spee in the lower arch, a majority of the leveling will be done after jaw surgery via the extrusion of the premolars.
- If the mandibular arch is fully leveled before surgery, then the bicuspid extraction spaces should also be closed before surgery.
- If a degree of lower arch leveling is to be accomplished after jaw surgery, then it is desirable to leave some of the bicuspid extraction space to be closed postoperatively.
- Passive surgical arch wires to be used for stabilization during surgery should be full-dimensional and rectangular.
- With effective plate and screw fixation at each osteotomy site, continuous intermaxillary fixation after surgery is not warranted. Nevertheless, the orthodontic placement of stable hooks throughout the arch wires is useful both at the time of surgery and to accomplish supportive vectored elastics postoperatively.

Immediate Presurgical Planning

The immediate presurgical planning takes into account collaborative clinical efforts between the orthodontist, the surgeon, the patient, and the patient's family that will have been ongoing since the initial consultation visits. Depending on the condition of the dentition and its supporting structures, the restorative dentist and the periodontist may also have been intricately involved.

Patient-specific medical and dental records are reviewed, which include (but are not limited to) the following: radiographs (e.g. computed tomography scans; panoramic, lateral, and posterior anterior cephalometric and periapical scans); photographs (facial and occlusal); and dental models.

Immediate presurgical records (i.e., within 2 to 6 weeks of surgery) will most importantly include facial measurements taken during the direct visual examination; alginate impressions of the maxilla and mandible; an accurate centric relation bite; and an accurate face-bow registration.

First, broad-stroke decisions are made regarding preferred vector changes for each jaw; only then are the precise millimeter distances and angular changes that are required in each jaw to achieve the desired result determined (see Chapter 12).[3,4,17,42] Analytic model planning is carried out on the articulated dental casts with use of the Erickson Model Table. Splints are constructed to assist with the achievement of the precise occlusion and the preferred facial aesthetics in the operating room (see Chapter 13).

During surgical planning for the individual with a primary mandibular deficiency growth pattern, it is known that bilateral sagittal split ramus osteotomies with advancement into a corrected overbite and overjet position will be required (Figs. 19-6 through 19-9).[6,21] An important consideration is whether or not surgical repositioning of the upper jaw (i.e., Le Fort I osteotomy) will also be useful to correct arch-width discrepancies; to further adjust the horizontal and vertical position of the maxilla; and to alter the maxillary plane (i.e., pitch orientation) and cant (i.e., roll orientation) (Figs. 19-10 through 19-15).[3,4,15,18,41,40,46,49,60] An assessment of the baseline chin morphology is also important. Anticipating the location of the pogonion after jaw repositioning and considering the advantage of an osseous genioplasty to achieve an enhanced horizontal

• **Figure 19-8** A woman in her late 20s was referred by an orthodontist for surgical evaluation. During her high school years, the patient underwent maxillary first bicuspid extractions with orthodontic retraction to neutralize the occlusion in the presence of mandibular deficiency. She now hoped to improve her profile aesthetics and to achieve long-term dental health. The patient agreed to an orthodontic and surgical approach. Orthodontic (dental) decompensation required opening the maxillary bicuspid extraction spaces for dental implants and crowns. The mandibular arch was also decompensated. The patient then underwent surgery that included bilateral sagittal split ramus osteotomies (horizontal advancement); osseous genioplasty (horizontal advancement); and an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication). **A,** Frontal views in response before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 19-9** A woman in her late 20s was referred by an orthodontist for surgical evaluation. During her teenage years, she underwent camouflage orthodontics to neutralize the occlusion, including maxillary first bicuspid extractions with space closure. She arrived for evaluation to improve the occlusion and to achieve enhanced profile aesthetics. She agreed to an orthodontic and surgical approach. Orthodontic (dental) decompensation required the proclination of the maxillary anterior dentition and mandibular first bicuspid extractions with the retraction of the anterior dentition. This was followed by surgery that included bilateral sagittal split osteotomies of the mandible (horizontal advancement); osseous genioplasty (horizontal advancement); and an anterior approach to the soft tissues of the neck (cervical flap elevation and neck defatting). **A,** Frontal views in repose before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Profile views before and after reconstruction.

• **Figure 19-11** A 16-year-old girl was referred for surgical assessment only after orthodontic treatment was well under way. She had undergone four bicuspid extractions and compensating orthodontics, but these were unsuccessful with regard to the neutralization of the occlusion. She was then recognized as having mandibular deficiency with a significant overjet, an anterior open bite, and obstructed nasal breathing. A degree of gingival recession on the labial aspect of the lower canines was appreciated. The maxillary incisors were procumbent but without space for further retraction. Reconstruction included a Le Fort I osteotomy in segments (horizontal advancement and transverse widening); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement); and septoplasty and inferior turbinate reduction. The patient's gingival recession which was present prior to surgery is being monitored. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

• **Figure 19-12** A 30-year-old woman was referred for surgical assessment only after orthodontic treatment was well under way. When the patient was between 9 and 15 years old, orthodontic growth modification and then a camouflage approach were carried out, but these were not successful. The current orthodontic treatment was flaring the maxillary anteriors even further forward. The patient was referred to this surgeon and agreed to a combined surgical and orthodontic approach. Orthodontic retraction of the maxillary anteriors was then initiated. With sufficient orthodontic (dental) decompensation, surgery was carried out, including bilateral sagittal split osteotomies of the mandible (horizontal advancement and counterclockwise rotation); maxillary Le Fort I osteotomy in segments (arch expansion, horizontal advancement, and minimal counterclockwise rotation); osseous genioplasty (horizontal advancement); and an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication). **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

• **Figure 19-14, cont'd G,** Computed tomography scan views before reconstruction that indicate congenital dysplasia of the condyle–glenoid fossa complex. **H,** Lateral cephalometric radiographs before and after treatment.

• **Figure 19-15** A 15-year-old girl was referred for surgical assessment only after orthodontic treatment was well under way. She had severe mandibular deficiency and microgenia, and she had already undergone four bicuspid extractions and a full course of orthodontic treatment. An anterior open bite with procumbent maxillary incisors remained. Evaluation was carried out, including a computed tomography scan, a sleep study, and speech and otolaryngology consultations. The computed tomography scan confirmed congenital dysplasia of the condyle–glenoid fossa complex without condylar resorption. Orthodontics were reinitiated, and surgical reconstruction was chosen. The surgical procedures included a maxillary Le Fort I osteotomy (horizontal advancement, vertical shortening, and counterclockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); and osseous genioplasty (horizontal advancement). A mild anterior open bite has recurred, but this had been stable for several years. A review of the immediate and late postoperative cephalometric radiographs confirmed a consistent sella–nasion–B-point angle without radiographic evidence of condylar resorption (i.e., no skeletal relapse could be documented). Dental relapse in the anterior dentition was felt to be the cause of recurrent malocclusion. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

and vertical position of the chin are important (see Chapter 37).

Basic Surgical Approach

In addition to lower jaw advancement (i.e., sagittal ramus osteotomies), maxillary surgery to correct arch-width discrepancies may be required for the individual with primary mandibular deficiency. This is generally accomplished by segmental maxillary osteotomies. Through the Le Fort I down-fracture, any needed improvement in the upper-lip-to-upper-tooth relationship can also be simultaneously carried out via the alteration of the vertical height. Any deficiencies in the horizontal position (i.e., projection) of the maxilla are also managed. The correction of a maxillary midline discrepancy (i.e., yaw), the aesthetic advantages of maxillary plane alteration (i.e., pitch), cant correction (i.e., roll), and intranasal procedures (i.e., septoplasty and inferior turbinate reduction) can also be simultaneously accomplished through the Le Fort I osteotomy (see Chapter 12).

In cases of only borderline maxillary deformity, limiting the surgery to the lower jaw is generally possible to manage the malocclusion and to address aesthetic aspects.

- When the decision is made to limit surgery to the mandible and with only a minimum arch-width discrepancy, the option of narrowing the mandible (i.e., a midline symphyseal split) may be considered.
- When only borderline maxillary vertical deficiency coexists (i.e., not enough to warrant a Le Fort I osteotomy), additional surgical vertical lengthening of the chin may be incorporated to achieve an aesthetic advantage.
- When mandibular deficiency is combined with a less than ideal clockwise rotated and vertically deficient maxilla, the surgically advanced mandible (without simultaneous Le Fort I osteotomy) may not achieve the preferred profile aesthetics (i.e., there will be a suboptimal A-point to B-point relationship in profile). In borderline cases, a vertical lengthening and a limited horizontal advancement osseous genioplasty may provide the necessary degree of aesthetic compensation.

COMMENT: When there are only borderline indications for maxillary surgery, the ability to fine-tune facial aesthetics with a compensating osseous genioplasty may exist (see Chapter 37).[48] Nevertheless, it is important to understand that a percentage of patients who present with primary mandibular deficiency will also have degrees of maxillary dysmorphology that are best served by double jaw surgery.

Postsurgical Orthodontic Maintenance and Detailing

If the patient has a presurgical habit of posturing the mandible forward (i.e., a dual bite), there may also be a tendency to do so during the immediate postoperative healing phase. Intermittent elastics are used during this time 1) to retrain the masticatory muscles, 2) to provide movement in the temporomandibular joints, 3) to increase patient comfort, and 4) to confirm the stability of the occlusion.

If segmental maxillary osteotomies were also carried out, a prefabricated splint will have been secured to the maxillary occlusal surfaces during surgery. The orthodontist sees the patient within 24 hours of splint removal (approximately 5 weeks after surgery) and replaces the maxillary sectional arch wires with a rigid continuous arch wire. The maxillary teeth are ligated together to maintain the arch form. The use of a transpalatal appliance or a palatal plate may also be used to stabilize and maintain the arch form if significant transverse expansion was carried

out.[12] Close orthodontic monitoring for skeletal and dental shifts during the first 6 months after surgery is essential (see Chapter 17).[1,8,9,10,16,22,26,33,54,56,63]

The postsurgical orthodontic objectives should be to bring the teeth into ideal occlusion and to maintain the surgical result. In the patient in whom the curve of Spee is to be fully leveled postoperatively, the use of vertical elastics to close the mid-arch open bites and for the full closure of the bicuspid extraction sites will also be priorities. This process can be initiated immediately after surgery.

Complications, Informed Consent, and Patient Education

The orthodontist is frequently asked to evaluate a preadolescent child who is presenting with primary mandibular deficiency. The clinician may attempt to alter nature's events through growth modification maneuvers.[53] Clinical studies now confirm limited success with a growth modification approach if the goal is to "normalize" the deficient lower jaw. The camouflage orthodontic approach that often follows may neutralize the occlusion, but it will not improve baseline upper airway dysfunction, and it will not enhance the appearance of a retrusive profile. Furthermore, it may have detrimental effects on the periodontium (see Figs. 19-1 through 19-5). The onus is on the clinician to communicate the shortcomings of these isolated orthodontic maneuvers to the patient and the family before beginning treatment.

After a combined surgical and orthodontic approach is agreed to, the clinician's ability to communicate the potential risks, complications, and benefits of the recommended coordinated plan to the patient and the family is essential (see Chapter 17).[19,24] The patient's and the family's informed decision to proceed provides the basis for shared responsibility of the outcome (see Chapter 7).

Temporomandibular Disorders: The Effects of Orthodontics and Orthognathic Surgery

Temporomandibular disorders (TMDs) include various symptoms and signs of the temporomandibular joint, the masticatory muscles, and related structures. The symptoms and signs may include a spectrum of referred head and neck pain; joint noise (e.g., popping, clicking, crepitus); reduced or altered mandibular movements (e.g., muscle spasm or disc displacement with or without reduction); condylar head erosion; and pain on direct palpation of either temporomandibular joint or of the masticatory muscles.

Occlusal features more likely to be associated with symptomatic TMDs include a centric relation to centric occlusion slide of more than 2 mm; overjets of more than 4 mm; and the presence of a skeletal anterior open bite. It is likely for these reasons that White and colleagues found that TMDs were significantly greater among patients with Class II skeletal deformities as compared with those patients with Class III deformities.[58] Westermark and colleagues studied a consecutive series of Class II patients to understand the effects of orthognathic surgery on the signs and symptoms of TMD.[57] Preoperatively, 43% of the patients reported subjective symptoms of TMD; postoperatively, 28% reported such symptoms. This difference suggests an overall beneficial effect of orthognathic surgery for many individuals with Class II mandibular deficiencies.[28] Interestingly, clinical studies indicate that patients with mandibular retrusion and TMD do not improve as much from an orthognathic correction as patients with a Class III skeletal pattern do (see Chapter 9).

Conclusions

In the American and Northern European populations, mandibular deficiency is the most frequently seen developmental jaw deformity. This results in an Angle Class II malocclusion with an excessive overjet and often with a deep overbite. The mandible and the chin region will be deficient, and the maxilla may also be deformed. The basic facial dysmorphology in an individual with primary mandibular deficiency is that of diminished vertical and horizontal strength in the lower third of the face. There will be lack of support for the overlying soft tissues that results in an overly obtuse neck–chin angle, with double-chin formation and early jowling. The tongue will be retropositioned within a small oral cavity and have negative effects on the airway. The laxity of the soft-tissue envelope only worsens throughout the normal aging process.

The correction of this frequently seen facial imbalance requires the orthodontic removal of dental compensations, often with extractions. Orthognathic surgery is performed for the achievement of a stable occlusion, long-term periodontal health, improvements in the upper airway, and the enhancement of facial aesthetics.

Developmental Class III skeletal problems generally result from maxillary deficiency in combination with relative mandibular excess. Through trial and error, it is now recognized that either growth modification in the preadolescent patient or camouflage treatment in the teenager or adult as a method of managing this type of dentofacial deformity is at best relatively ineffective. In addition, even mild degrees of a Class III facial appearance are aesthetically noticeable as unattractive by the general population.[76] Therefore, the perceived need for treatment (i.e., de facto orthognathic surgery) for the Class III patient—whether by the public, the evaluating clinicians, the affected individual, or the patient's family and friends—will be high.[13,72,78,125]

There is a strong family tendency for a Class III skeletal pattern. The so-called "Habsburg jaw" within the royal European family is well documented.[58,104,106,122,124] The frequency of Class III skeletal patterns among white people of European or North American ancestry is reported to have a prevalence in the low single digits. There is a somewhat higher prevalence of Class III skeletal patterns among Africans than among Caucasians.[27] Data from Japan, Korea, and China confirm a more frequent Class III pattern among Asians than among any other subgroup (i.e., >4%).[28,117] Incidence rates of Class III malocclusion of as high as 13% have been reported in specific regions of Asia.[119] Lew and colleagues examined occlusal parameters in 1050 Chinese schoolchildren who were between 12 and 14 years old.[48] They found an incidence of 12.6% for Class III malocclusion, 58.8% for Class I occlusion, and 21.5% for Class II malocclusion. Samman and colleagues investigated 300 Chinese individuals residing in Hong Kong who were known to have dentofacial deformities and who had been referred to an "orthognathic surgery clinic."[91] After excluding those individuals with cleft lip and palate, 222 study patients remained. Forty-seven percent of these individuals (n = 104) were found to have a Class III skeletal malocclusion.

Despite hereditary tendencies, the development of a Class III jaw disharmony is believed to be multifactorial and complex.[8,33,39,57] Alternatively, it has been documented that environmental factors have a significant effect on vertical facial growth (see Chapter 21). The combination of an individual's hereditary tendency toward a Class III skeletal pattern and a longstanding, forced mouth breathing, open-jaw posture during growth explains the occasional occurrence of a long face growth pattern (i.e., excess vertical growth) with Class III negative overjet malocclusion.[29] An outlier for a Class III skeletal pattern is the impaired midface growth that is seen in many individuals from all backgrounds with repaired cleft palates (see Chapters 32, 33, and 34). Another commonly seen clinical pattern is the individual with maxillary vertical deficiency and a prominent pogonion (i.e., pseudoprognathism) as a result of "over closure" (see Chapter 23).[97,99,109]

An additional source of data regarding the prevalence of individuals with skeletal Class III is the National Health and Nutrition Examination Survey III, a large-scale epidemiologic survey of the U.S. population that was carried out during the 1990s (see Chapter 3).[77] The data from this study confirm that Class III problems increase from early childhood through adolescence.[1,18] This can be explained by the expected late growth spurt in the mandible as compared with the maxilla. The study also confirmed that the presence of 2 mm or more of negative overjet is about twice as likely to occur among African Americans than among Caucasian Americans or Mexican Americans. Data from a U.S. public health survey of youths between the ages of 12 and 17 years indicates that about 14% have a mandibular first molar that is mesial in relation to the maxillary first molar.[42]

With regard to treatment, by the late 1800s, both Edward Angle, an orthodontist, and Vilray Blair, a surgeon, recognized that orthodontic treatment alone could not solve the Class III skeletal problem.[15] Angle suggested that the only possible way to correct a true mandibular protrusion was with a combination of orthodontics and surgery.[2] By the late 1800s, the initial orthognathic procedures were carried out to "set-back" the prominent mandible (see Chapter 2).

Functional Aspects

- Predictable articulation errors in speech result from a Class III malocclusion (see Chapter 8).
- Chronic obstructed nasal breathing is commonly seen in the presence of maxillary deficiency (see Chapter 10).
- Characteristic difficulties with swallowing and chewing as a result of a Class III malocclusion are expected (see Chapter 8).
- Wide lip separation (often with upper lip hypotonia) and mentalis strain required for lip seal are commonly seen in the presence of a significant negative overjet.
- Detrimental long-term effects on the dentition and the periodontium that result from a Class III malocclusion (secondary occlusal trauma), dental crowding, or previous camouflage orthodontics are often seen (see Chapter 6).
- The incidence of temporomandibular disorder (TMD) may be higher among these patients than among individuals with normal jaw harmony and occlusion (see Chapter 9).

Clinical Characteristics

Profile View

- Long chin–neck length and acute angle with a visually accentuated inferior border of the mandible
- Prominent chin with a reduced labiomental fold
- Protrusive and thick lower lip and vermillion
- Sunken-appearing midface (A negative vector relationship between the ocular globe and the lower eyelid as a result of anterior maxillary deficiency is a frequent finding.)
- Deflated, short, hypotonic appearance of the upper lip, with a thin vermillion
- Acute nasolabial angle
- Columella of the nose oriented more horizontally

Frontal View

- Sunken-appearing cheeks (i.e., the impression of flat cheek bones)
- Middle one third of the face appears flat and long
- Increased scleral show (i.e., pulling down of the lower lids)
- Narrow alar base with paranasal flattening
- Flat and relatively short upper lip with reduced vermillion exposure
- Normal to deficient maxillary tooth to upper lip relationship frequently seen
- Mandible appears prominent
- Reduced labiomental fold

Dental Characteristics

- Minimal attached gingiva over the labial aspects of the mandibular anterior teeth is frequently seen (see Chapter 6).
- Mandibular incisors are usually upright or lingually inclined.
- Interdental spacing with flared mandibular incisors may also be seen, especially in the presence of an anterior open bite with lip incompetence.
- Class III malocclusion (molar and canine) with anterior open bite, negative overjet, and posterior crossbites is frequent.
- Narrow maxillary arch width is seen as excess negative space in the buccal corridors.
- Dental crowding with flared maxillary incisors is frequent.

Radiographic Findings

- Maxillary horizontal deficiency
- Concave anterior maxilla consistent with a negative vector relationship of the ocular globe to the lower eyelid
- Flat, counterclockwise-rotated maxillary plane
- Procumbent maxillary incisors
- Flat base of the nose with retrusive pyriform rims
- Altered lower anterior facial height (either short or long)
- B-point is anterior to or in front of A-point in profile (i.e., natural head position)
- Negative overjet to the occlusion
- Prognathic-appearing mandible
- Lingually inclined mandibular incisors frequently found
- Chin morphology varies, but it is generally dysmorphic. Frequent patterns of chin dysmorphology include vertical excess with either a prominent or flat pogonion.

The Role of Growth Modification in the Preadolescent Patient

Since the mid 1800s, clinicians have developed and used devices to attempt to correct and prevent a worsening Class III skeletal pattern during childhood. Despite this extensive history, little long-term success has been documented involving the use of these devices. Techniques have included use of a *chin cup* to "hold back" the mandible; a *face mask* to "grow" the maxilla; and, more recently, the use of *skeletal anchorage devices and elastics* in an attempt to do both.

Most studies have found no difference in the ultimate size of the mandible between children with Class III conditions who were treated with a *chin cup* and those who were not.[105] Wylhelm-Nold and colleagues presented some evidence that the use of the chin cup in preschool-aged children was able to decrease mandibular anterior growth if good compliance was achieved.[123] Unfortunately, this did not prevent the mandible from continuing an excess growth pattern later during childhood, after the chin cup treatment was stopped. In fact, a rebound accelerated growth effect was documented. What chin cup therapy may accomplish is a change in the growth vector of the mandible, with more downward and backward (clockwise) rotation.[37] These secondary changes have their own negative effects on facial morphology and occlusion (i.e., the law of unintended consequences).

With the realization that the presenting maxillary deficiency should be the primary focus of the correction for most skeletal Class III individuals, growth modification moved toward methods of stimulating the upper jaw. The *Delaire face mask* has been used extensively to pull the maxilla forward.[24] The work of Baccetti and McNamara confirmed that use of the Delaire face mask for the individual with maxillary deficiency is more likely to have effect when it is used before the patient is 8 years old.[6,21,92] After this age, tooth movement (dental compensation) and mandibular clockwise rotation will be the likely consequences of this form of treatment rather than the hoped for horizontal maxillary projection. In addition, many children experience recurrence of the deformity after face mask therapy is discontinued. It is unlikely that face mask (for the maxilla) and chin cup (for the mandible) interventions will be effective in the long term for preventing the need for orthognathic surgery in all but mild cases. An accepted guideline is that more than 2 to 4 mm of reverse overjet in the preadolescent child indicates that surgery will eventually be needed if both facial and dental correction are sought.

DeClerck and colleagues used orthopedic traction on the maxilla and compression on the mandible with temporary mini-plate *skeletal anchorage and elastics* in a limited number (n = 3) of 10- to 11-year-old children presenting with skeletal Class III malocclusions.[25] Pure bone-borne orthopedic forces were applied with intermaxillary elastics on the skeletally anchored mini-plates. This approach was shown to either enhance midface growth or to hold back the mandible; in any case, the intent was to produce a corrected overjet. Although the authors were encouraged, many unknowns remained, including the ideal age for this type of orthopedic traction; the effect of the direction of force on the rotation of the palatal and mandibular planes; the long-term effects on the temporomandibular joints; and the need for retention to prevent catch-up growth of the mandible or relapse of the maxilla afterward. DeClerck's ongoing prospective clinical trial of this promising work on a larger sample of patients (as well as the work of other independent researchers) will help to answer these questions and to determine the true effectiveness of a growth-modification approach that involves temporary skeletal anchorage and elastics.[21,92]

Orthodontic Camouflage Approach

The decision to proceed with an orthodontic camouflage approach frequently implies that orthopedic growth modification mechanisms to overcome the Class III pattern were either ineffective earlier during the patient's life or that the patient presents to the orthodontist at an age at which such mechanisms are not feasible. In the adolescent or adult, when a significant reverse overjet remains, the possibility of achieving even the limited parameter of a neutralized occlusion with the use of only orthodontic maneuvers is questionable. In fact, doing so may require the further displacement of the teeth outside of the supporting alveolar bone as a means of compensation for the underlying jaw discrepancy. The extraction of the mandibular first premolars in combination with Class III elastics and extraoral forces on the maxilla (i.e., the proclination of the maxillary incisors) will improve the occlusion for the Class III patient; however, treatment generally falls short of expectations and rarely produces acceptable facial aesthetics. Even minimal retraction of the lower incisors often magnifies the chin's prominence, which is likely a primary reason why the patient sought treatment. Furthermore, camouflage orthodontics will not succeed in altering any combined vertical skeletal problems. In fact, the orthodontic mechanisms that are used to reposition the dentition often extrude the posterior teeth, thus further accentuating the vertical facial disproportion.

Individuals who present to the orthodontist with a Class III skeletal pattern will usually have dental compensation that developed as an adaptive biologic mechanism during growth. Typically, the upper incisors are at least somewhat proclined relative to the maxillary basal bone. The lower incisors are often overly upright relative to the basal bone of the mandible. If an orthodontic camouflage approach is chosen, then the upper incisors are proclined, and the lower incisors are retropositioned even further.

It is not uncommon for the orthognathic surgeon to see an adult in consultation who is emotionally exhausted after having undergone failed growth modification followed by disappointment after additional years of camouflage orthodontics. The individual may present with 1) significant residual malocclusion (i.e., effects on speech, swallowing,

and chewing) 2) deteriorating periodontal health (i.e., crest bone loss and gingival recession associated with lower anterior and upper posterior teeth), 3) often with chronic upper airway obstruction (i.e. deviated septum, hypertrophic inferior turbinates, and tight nasal apertures) and 4) self-esteem and body image issues related to the facial disproportion and disappointment with failed treatment (Figs. 20-1 through Fig. 20-4).

All too often, the orthodontic camouflage approach was centered on the achievement of a neutralized occlusion as the primary objective, without full disclosure to the patient and his or her family. If the goals of treatment are to achieve long-term ideal dental health, improved facial aesthetics and an open upper airway, few treatment plans for the Class III patient would include a camouflage approach. Clear contraindications to an orthodontic camouflage approach include the following:

- Moderate or severe Class III patterns (i.e., >4 mm of reverse overjet)
- Moderate to severe vertical skeletal discrepancies
- Significant dental crowding in the lower jaw and significant anterior dental protrusion in the upper jaw
- A concern that the planned orthodontic mechanics may cause periodontal deterioration
- A desire for enhanced facial aesthetics
- A need to open the upper airway

Surgical Camouflage Approach

Some orthodontists have been buoyed in their efforts to neutralize the occlusion in the individual with a skeletal Class III condition on the basis of a belief that limited cosmetic surgery can improve the facial appearance and thus avoid major orthognathic procedures. Attempts at surgical camouflage for the patients with a Class III skeletal pattern may include a combination of reduction genioplasty; onlay grafting to the midface; upper lip augmentation; lower lip reduction; and neck and chin soft-tissue procedures. In general, these camouflage surgical techniques are ineffective, irreversible, and disappointing.

Often, a prominent chin and apparent flat cheek bones are perceived by the patient to be the aesthetic issues. Although a reduction genioplasty seems to be a logical approach, the surgical reduction of the prominent chin as an isolated procedure in the absence of orthognathic surgery rarely satisfies the facial aesthetic concerns. "Setting back the chin" generally leads to drooping (i.e., ptosis) of the associated soft tissues; irregularities of the mentalis muscles when in function; and a double-chin appearance of the neck. *Submental lipectomy* may then be considered in an attempt to improve the chin ptosis and the appearance of the neck, but with only limited effects. *Onlay grafts or implants* involving the anterior maxilla have been used in an attempt to camouflage the midface deficiency. These perinasal implants run the risk of looking and feeling unnatural. *Augmentation of the zygomas and the infraorbital rims* is generally misguided and will produce an unnatural and "operated" look. *Upper lip augmentation* and *lower lip reduction* procedures in the Class III patient also tend to look and feel unnatural.

To be fair to the patient and his or her family, the limitations of compensating orthodontics followed by surgical camouflage should be disclosed before the initiation of treatment.

Definitive Reconstruction

Timing of Orthognathic Surgery

Skeletally immature individuals with true mandibular excess can be expected to outgrow any early orthodontic or surgical corrections and later require further treatment.[7,17,83,90] Indirect methods of assessing growth maturity (e.g., a hand–wrist film to determine bone age) are not accurate enough to be used in isolation for planning the timing of surgery. A reasonable method to assess growth maturation is through the analysis of *serial lateral cephalometric radiographs*. These radiographs can be used in two ways: for a cervical vertebral analysis or to make sequential direct mandibular measurements. Surgery is delayed until the deceleration of growth can be documented. The use of a *quantitative condylar head bone scan* can also be helpful to evaluate the growth of the mandible in the adolescent, but both false-positives and false-negatives may occur. If the Class III condition is largely the result of maxillary deficiency, gauging the preferred timing of surgery is more straightforward, because the late postsurgical growth of the mandible is less likely (see Chapter 17).

Alexander and colleagues completed a study of craniofacial growth changes in Caucasians with untreated Class III malocclusions by using longitudinal cephalometric records (n = 103).[1] In girls, the mandibular growth spurt generally occurred between the ages of 10 and 12 years. In boys, the growth spurt was usually between the ages of 12 and 15 years. In some of the Class III subjects, limited degrees of mandibular growth relative to that of maxillary growth were documented to continue after the adolescent spurt. After the age of 13 years in girls and 15 years in boys and until closer to the age of 17 years, annual increments of mandibular growth were often between 1.5 mm and 2.0 mm, whereas increments of midface length dropped to less than 1 mm. The authors concluded that the differential growth behavior of the two jaws among individuals with Class III conditions may result in recurrent jaw disharmony and malocclusion when orthodontic or surgical treatment is undertaken before or during puberty.

Pre-Orthodontic Periodontal Checklist (see Chapter 6)

- Assess for active gingivitis or periodontitis and the need for treatment.

Text continued on p. 694

• **Figure 20-1** A 34-year-old male arrived for the evaluation of a longstanding jaw deformity with malocclusion, chronic obstructive nasal breathing, and periodontal issues. Since his early childhood years, the patient was known to have a maxillary deficiency with a relative mandibular excess growth pattern. The family elected a camouflage orthodontic approach that included four bicuspid extractions and the introduction of dental compensation in an attempt to neutralize the occlusion when the patient was 10 to 15 years old. He is a forced mouth breather as a result of increased nasal airway resistance. The patient underwent septoplasty when he was 20 years old, but significant improvement of the airway did not occur. His general dentist confirmed labial bone loss and gingival recession of the mandibular anterior and maxillary posterior dentition. He was referred to this surgeon, and a comprehensive orthognathic and dental rehabilitation approach was selected. Consultation with a periodontist, an orthodontist, and an ear, nose, and throat specialist was carried out. The patient was confirmed to have residual deviation of the septum and enlarged inferior turbinates, which explained the continual difficulty that he had breathing through his nose. A degree of root resorption of the anterior dentition was confirmed. The need for gingival grafting to attain improved root coverage and to generate a wider band of attachment was recommended for tooth nos. 3, 11, 14, 19, 20, 23 through 26, 29, and 30. This will be followed by the orthodontic removal of dental compensation and then orthognathic and intranasal procedures to improve long-term dental health, to enhance facial aesthetics, and to open the upper airway. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile facial and lateral cephalometric radiograph before retreatment. **C,** Panorex radiograph before retreatment.

• **Figure 20-2** A 26-year-old man arrived for surgical evaluation. Since the mixed dentition, he had been recognized as having a developmental jaw deformity characterized by maxillary deficiency in combination with relative mandibular excess. Camouflage orthodontic treatment that included four bicuspid extractions was carried out when the patient was between 12 and 16 years old. A residual Class III negative overjet with an anterior open-bite malocclusion remains. The patient has never been able to breathe well through the nose as a result of septal deviation and inferior turbinate enlargement. Secondary occlusal trauma resulted in the need for root canal therapy and crowns in all four posterior quadrants. There is labial bone loss and gingival recession associated with the anterior mandibular teeth. A comprehensive dental rehabilitative and reconstructive approach will require periodontal evaluation and treatment followed by orthodontic decompensation and then by jaw and intranasal surgery. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile facial view and lateral cephalometric radiograph before retreatment. **C,** Panorex radiograph before retreatment.

• **Figure 20-3** A 30-year-old man arrived for the evaluation of a longstanding jaw deformity with malocclusion, chronic obstructive nasal breathing, and an awareness of periodontal issues. Since his early childhood years, he was known to have a jaw deformity with malocclusion, including an anterior open bite. When he was between 8 and 12 years old, he underwent orthodontic camouflage treatment in an attempt to close the open bite; this included full bracketing and the use of heavy anterior elastics. By the time that he graduated from high school, he was conscious of a significant recurrent anterior open bite with dental crowding. Throughout his college years, he was aware of gingival recession on the labial aspect of many of the anterior teeth of the maxilla more so than the mandible. He was sent by his general dentist for an orthodontic evaluation and then to this surgeon for an opinion. The patient was referred for periodontal evaluation with confirmation of significant labial bone loss of the anterior dentition (more so on the maxilla than the mandible) and gingival recession. A comprehensive approach was recommended; this would include gingival grafting and four bicuspid extractions, with orthodontic retraction of the anterior dentition into the solid alveolar bone. This would be followed by jaw reconstruction, finishing orthodontics, and periodontal surveillance. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile facial view and lateral cephalometric radiograph before retreatment. **C,** Panorex radiograph before retreatment.

• **Figure 20-4** A 29-year-old man arrived for the evaluation of a longstanding developmental jaw deformity characterized by maxillary deficiency with relative mandibular excess. There is malocclusion and chronic obstructive nasal breathing. By the time he was 13 years old, he was referred by his pediatric dentist to an orthodontist for the evaluation of a Class III negative overjet malocclusion. He then underwent a 2-year course of compensatory orthodontics in an attempt to neutralize the occlusion. He was left with an Angle Class III negative overjet and early signs of gingival recession. The patient also has a history of stress-induced asthma and chronic obstructed nasal breathing. He uses Flonase, Singulair, and other medications in an effort to open the nasal airway, and he is also being seen by an allergist. For his gingival recession, he was referred to a periodontist, and connective tissue grafting was carried out for the lower anterior dentition on several of the maxillary posterior teeth. An orthodontic consultation confirmed crowding, the proclination of the maxillary anterior dentition, and uprighted mandibular anterior teeth. Evaluation of the upper airway documented a deviated septum and hypertrophic inferior turbinates. An orthodontic and surgical approach was recommended to limit further secondary dental trauma, to stabilize the periodontium, and to correct the occlusion. **A,** Frontal facial and occlusal views before retreatment. **B,** Profile facial and lateral cephalometric radiographs before retreatment. **C,** Panorex radiograph before re-treatment.

- Assess the current level of oral hygiene and the need for a home care program.
- Assess for the effects of occlusal trauma and malocclusion on the periodontium.
- Assess the level of attached gingiva and the need for augmentation.
- Confirm the adequacy of the alveolar bone and the need to create space with the use of extractions.
- Assess the need for restorations to remove decay, to replace deficient enamel, and to achieve a healthy gingival interface.

Orthodontic Preparation for Orthognathic Surgery

1. Before orthodontic decompensation, assess the level of attached gingiva, the position of the labial and lingual plates, and the alveolar crest heights. Consider the effects of any planned orthodontic maneuvers on the periodontium.
2. Make decisions about the tooth (root) size to alveolar volume discrepancies in each arch and the need for extractions to establish and preserve periodontal health.
3. Create a plan (i.e., separate surgical and orthodontic objectives) to achieve preferred anteroposterior and vertical incisor positions in the maxilla and the mandible.
4. Understand how the orthodontic objectives become more limited when they are combined with the planned surgical procedures (e.g., maxillary segmentation, bimaxillary osteotomies) to then achieve the final desired arch form, midline positioning, occlusion, and facial symmetry and proportions.
5. Make decisions about orthodontic mechanics and anchorage requirements to achieve the chosen objectives.
6. At the end of the presurgical orthodontic phase (i.e., 4 to 6 weeks before surgery), full-dimensional stabilizing (i.e., passive) arch wires should be in place. The placement of surgical hooks can be done just before surgery.

Leveling the Mandibular Arch

When an accentuated curve of Spee is present in the lower arch of a patient with Class III malocclusion, it is managed through a combination of intrusion of the incisors and extrusion of the premolars or molars.[20,49] In preparation for surgery, repositioning the lower incisors forward is generally advantageous for the Class III skeletal pattern. Therefore, lower arch extractions are rarely indicated. If limited labial bone is present, a periodontal evaluation is recommended before the incisors are orthodontically moved forward. If gingival recession has occurred or if the gingiva is genetically inadequate, augmentation grafting procedures are indicated (see Chapter 6).

Leveling of the Maxillary Arch

If the upper arch is narrow, then orthodontic leveling is performed in segments in anticipation of surgical management.[8,14,16,22,71,88,95,114] If the curve of Spee is excessive as a result of vertical skeletal dysplasia, then leveling is also done in segments in preparation for surgical correction (see Chapter 17).

In the presence of maxillary deficiency, limited space to uncrowd the upper teeth may leave the roots tipped outside of the solid alveolar housing. In this circumstance, maxillary first bicuspid extractions with space closure before surgery is preferred. With only borderline crowding, extractions are often not carried out. Limited dental space deficiency can often be managed through the judicious use of interproximal reduction. In addition, the aesthetic consequences of mildly proclined incisors (i.e., A-point to B-point discrepancy in profile) can be improved via the clockwise rotation of the maxillomandibular complex at the time of surgery (see Chapters 12 and 13).

Immediate Presurgical Planning

The immediate presurgical planning takes into account collaborative clinical efforts between the orthodontist, the surgeon, the patient, and the patient's family that will have been ongoing since the initial consultation visits.[32,74,75,84,93,98] Depending on the condition of the dentition and the supporting structures, the restorative dentist and the periodontist may also have been intricately involved.

Patient-specific medical and dental records are reviewed, including radiographs (e.g., computed tomography scans; panoramic, lateral, and posteroanterior cephalometric and periapical radiographs); photographs (e.g., facial, occlusal); and dental models.

Immediate presurgical records (i.e., within 2 to 6 weeks of surgery) will most importantly include facial measurements taken during direct visual examination; alginate impressions of the maxilla and the mandible; a centric relation bite registration; and a face-bow registration.

First, broad-stroke clinical decisions are made involving the preferred vector changes for each jaw; only then are the precise millimeter distances and angular changes required for each jaw to achieve the desired results determined (see Chapter 12). Analytic model planning is carried out on the articulated dental casts with use of the Erickson Model Table. Splints are constructed to assist with the achievement of the precise occlusion and the preferred facial aesthetics in the operating room (see Chapter 13).

During surgical planning, consideration should be given to the following eight aspects (see Chapter 12):

1. *Assess the degree of horizontal advancement required in the midface as measured at the maxillary incisal edge.*

   A nose that appears to be excessively large in a patient with a skeletal Class III condition favors the horizontal advancement of the maxilla. Repositioning and projecting the upper jaw forward will diminish the apparent size of the nose. An obtuse nasolabial angle with a hypotonic upper lip also favors maxillary

horizontal advancement; doing so will improve the nasolabial angle and provide fullness to the upper lip. A constricted nasal aperture and a depressed base of the nose also benefit from maxillary advancement. A fully projected midface fills out the pyriform rims and provides needed width to the alar base. For these same reasons, the individual who appears to have flat upper cheeks with pulled-down lower eyelids (i.e., scleral show) benefits from Le Fort I osteotomy with advancement and clockwise rotation.

2. *Assess the degree of vertical change required in the midface as measured at the maxillary incisal edge.*

   Individuals with maxillary deficiency and relative mandibular excess generally present with varying degrees of either vertical midface excess or deficiency. A decision regarding the preferred aesthetic vertical position of the maxillary incisors should be made. Anterior vertical lengthening and clockwise rotation are frequent preferred vector changes used to achieve enhanced midface aesthetics in the patient with a Class III growth pattern.
3. *Assess the potential advantages of clockwise rotation of the maxillary plane to achieve preferred A-point to B-point positioning (i.e., pitch orientation).*

   Clockwise rotation of the maxillomandibular complex is generally required to enhance a positive vector relationship between the ocular globe and the lower eyelid.
4. *Clarify any maxillary midline to facial midline discrepancies and their planned correction (i.e. yaw orientation).*

   When doing so, consideration is given to the maxillary yaw orientation and the anticipated yaw effects on facial symmetry.
5. *Identify any canting (i.e., roll orientation) of the maxilla and its planned correction.*

   If more than 4 degrees of cant are present, this will be noticeable to even the untrained eye at conversational distance (see Chapter 12).
6. *Identify the advantages of segmentation of the upper jaw to achieve the preferred maxillary arch form and occlusion.*

   Determine the preferred location of the interdental osteotomies to best achieve the patient's objectives. This will have been discussed with the treating orthodontist before the initiation of treatment.
7. *Assess the baseline chin morphology.*

   Anticipate the location of the pogonion after jaw repositioning. Consider the advantages of osseous genioplasty and the preferred ultimate horizontal and vertical position of chin.
8. *Assess the baseline pyriform rim, floor of nose, and anterior nasal spine morphology.*

   Anticipate the location of these structures after maxillary repositioning and the advantages of recontouring them to achieve the ultimate objectives.

Basic Surgical Approach

Regardless of the cause of the Class III skeletal pattern, the common aesthetic impression in profile is of a flat or concave midface with a long and forward-projecting chin.[89] The classic dentofacial deformity of maxillary deficiency with relative mandibular excess will require at a minimum a Le Fort I osteotomy with horizontal advancement.[30,31,38,62,85,86,112] The need for additional vector changes in the maxilla should always be considered (e.g., transverse widening, vertical adjustment, maxillary midline to facial midline correction, cant correction, clockwise maxillary plane rotation).[121]

The Le Fort I osteotomy (often performed in segments) with three-dimensional repositioning is generally combined with sagittal split ramus osteotomies to place the distal mandible into ideal occlusion at the new maxillary location.[9-12,50-52,63-66,70,87,94,110,113] In most cases, the full overjet deficiency is corrected in the maxilla. Clockwise rotation of the maxilla and the mandible will generally leave the mandibular incisor unchanged in the sagittal (i.e., horizontal) plane. However, the pogonion will have moved posteriorly.

An osteotomy of the chin with horizontal or vertical change is also frequently desirable.[36] If chronic nasal obstruction is present, then procedures to improve the airway in accordance with the physical examination (i.e., septoplasty, inferior turbinate reduction) may be simultaneously accomplished (Figs. 20-5 through Fig. 20-20).[73,75]

In general, well thought out maxillary surgical maneuvers (i.e., horizontal advancement, clockwise rotation) will also correct the presenting negative vector relationship between the ocular globe and the lower eyelid. In doing so, the overlying cheek and periorbital soft tissues are immediately enhanced. This also limits the unattractive eyelid and midface aging effects that would otherwise occur (i.e., soft-tissue descent, rounding of the palpebral fissure, lengthening of the lower lid, loss of cheek region soft-tissue prominence; see Chapter 25).

When limiting the surgery to one jaw (either through mandibular set-back or Le Fort I advancement), the immediate correction of the occlusion may be possible, but a suboptimal outcome is likely. A one-jaw approach is rarely preferred from the overall perspective of facial aesthetics, occlusal stability, and upper airway management. A Le Fort I osteotomy in combination with mandibular ramus osteotomies that incorporates clockwise rotation of the maxillomandibular complex is generally needed to achieve midface fullness, to improve the projection of the nasal tip and, to enhance the upper lip to tooth aesthetics (see Figs. 20-5 through 20-20).

Demetriades and colleagues confirmed the clinical importance of considering the airway when formulating a treatment plan for the correction of a skeletal Class III pattern.[26] They reported on 26 patients who presented with developmental dentofacial deformities that were

• **Figure 20-5** A 17-year-old high school student was referred by his orthodontist for surgical evaluation. A non-extraction orthodontic approach had previously been carried out, without success. The Class III negative overjet anterior open-bite malocclusion required redo orthodontics and jaw surgery. Because the patient had a lifelong history of nasal obstruction and consistent physical findings (i.e. septal deviation and inferior turbinate hypertrophy), intranasal procedures were also planned. When orthodontic decompensation was complete, the patient's surgery included maxillary Le Fort I osteotomy in segments (arch expansion, horizontal advancement, vertical lengthening, and clockwise rotation); sagittal split ramus osteotomies (limited corrections); osseous genioplasty (vertical reduction and minimal horizontal advancement); and septoplasty and inferior turbinate reduction. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

• **Figure 20-10** A 17-year-old high school student was referred by his orthodontist, who requested surgical evaluation for a Le Fort III advancement. The Class III negative overjet malocclusion with maxillary deficiency gave the impression of flat cheekbones and infraorbital rims. Evaluation confirmed that the patient's deformity was limited to the maxilla and the mandible. Because the patient had a lifelong history of nasal obstruction and consistent physical findings, intranasal procedures were also required. When preparatory orthodontics were complete, the patient's surgery included maxillary Le Fort I osteotomy (horizontal advancement, vertical lengthening, and clockwise rotation); sagittal split ramus osteotomies (setback and clockwise rotation); osseous genioplasty (vertical reduction); and septoplasty and inferior turbinate reduction. Note the aesthetic advantage of the maxillomandibular clockwise rotation in the presence of baseline incisor procumbancy. This rotation projects the pyriform rims forward and sets back the pogonion. The orthodontic over-retraction of the lower incisors resulted in labial bone loss and gingival recession. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

characterized by maxillary deficiency in combination with relative mandibular excess. The patients were divided into two groups. All patients underwent mandibular ramus osteotomies with a degree of set-back. The Group 1 study patients (n = 13) underwent mandibular set-back of 5 mm or more without simultaneous Le Fort I osteotomy. The Group 2 study patients (n = 13) underwent limited mandibular set-back, but their procedures were performed in combination with Le Fort I advancement. All study patients underwent preoperative and postoperative lateral cephalometric radiographs at standard intervals. Any changes that occurred in the position of the hyoid bone, the distance of the palate to the posterior nasal spine, the retrolingual space, and the hypopharyngeal space were measured from the postoperative radiographs. Preoperative and postoperative portable polysomnography were also carried out. The study confirmed that mandibular retropositioning of 5 mm or more can significantly decrease the posterior airway space and cause mild to moderate obstructive sleep apnea. The study also suggested that, when a limited mandibular set-back is carried out in combination with maxillary Le Fort I advancement, significant negative effects on the posterior airway space are likely prevented.

Postsurgical Orthodontic Maintenance and Detailing

The surgeon's effective management of the patient's in-hospital and at-home convalescence during the initial healing period (i.e., 5 weeks) is essential for a successful outcome (see Chapter 11). Cephalometric and Panorex radiographs and facial and occlusal photographs are obtained at standard postoperative intervals to document progress. We prefer to take these records at the 5-week postoperative interval as a matter of routine.

If segmental maxillary osteotomies were carried out, a prefabricated surgical splint will have been secured to the

maxillary occlusal surfaces during the operation. The orthodontist sees the patient within 24 hours of splint removal at approximately 5 weeks after surgery, and he or she replaces the maxillary sectional wires with a rigid continuous arch wire. The teeth are then ligated together to maintain the arch form. The use of a transpalatal wire or an acrylic palatal plate may also be used to stabilize the arch form if significant transverse expansion was carried out. Close orthodontic monitoring for skeletal and dental shifts and detailing during the first 6 months after surgery is essential.

Complications, Informed Consent, and Patient Education

The orthodontist and the surgeon are frequently asked to evaluate jaw disharmonies and malpositioned teeth and then to attempt to alter nature's events. With an understanding of the natural progression of the uncorrected skeletal Class III dentofacial deformity and knowledge of how specific interventions will affect head and neck function and facial aesthetics, predictable results are generally achieved.

Complications and patient dissatisfaction will always occur in a small percentage of individuals.[4,23,44,46,47,53,54,120] The clinician's ability to communicate the potential risks and complications, the alternative approaches available, and the benefits of the recommended treatment plan to the patient and the family is essential to achieve a favorable result. When the patient, the family, and all treating clinicians are fully informed, shared responsibility for the treatment outcome is more likely (see Chapter 16).

Malocclusion after Orthodontics and Orthognathic Surgery

There are inherent biologic challenges to the orthodontic movement of the teeth in the alveolar process and to the surgical repositioning of the jaws or jaw segments in the individual with maxillary deficiency and relative mandibular excess. These include the technical aspects of the repositioning, the initial healing requirements, and the difficulties associated with the long-term maintenance of the mechanically relocated teeth, jaws, and jaw segments. When following sound biomechanical and aesthetic principles, clinicians carry out orthodontic treatment and surgical procedures and then effectively maintain the results, in most cases. Potential intraoperative technical difficulties associated with sagittal split ramus osteotomies of the mandible and maxillary Le Fort I osteotomies can result in an immediate (i.e., early) malocclusion; however, these difficulties are generally preventable (see Chapter 17).*

Timing the surgery to limit ongoing mandibular growth afterward is usually possible, but it is more problematic for the skeletal Class III patient than the Class II patient (see Chapter 17). Significant condylar resorption after orthognathic surgery is rarely seen in the skeletal Class III patient (see Chapter 36).

Proffit and colleagues make a compelling argument that for the Class III patient, when the orthognathic procedure is a mandibular set-back only versus two-jaw surgery then relapse at the ramus osteotomy site is a common occurrence.[79,80] Research confirms better long-term skeletal and occlusal stability when two-jaw surgery (i.e., maxillary advancement with limited mandibular setback) is performed for the management of most Class III skeletal patterns.[81]

All of these factors must be taken into account to best achieve and then maintain the desired results.

Temporomandibular Disorders: The Effects of Orthodontics and Orthognathic Surgery

It is estimated that an average of 32% of the population reports at least one symptom of TMD, whereas an average of 55% demonstrate at least one clinical sign. TMD includes various signs and symptoms of the temporomandibular joint, the masticatory muscles, and related structures. The signs and symptoms may include a spectrum of referred head and neck pain; joint noise (e.g., popping, clicking, crepitus); reduced or altered mandibular movements as a result of muscle spasm or disc displacement, with or without reduction; condylar head erosion, and pain on direct palpation of either of the temporomandibular joints or the masticatory muscles.[3,5]

Occlusal factors (i.e., degrees of malocclusion) are often claimed to be associated with TMD. Interestingly, the correction of a skeletal Class III jaw deformity through orthodontics and orthognathic surgery often relieves the signs and symptoms of TMD, but this is not predictable for each individual patient (see Chapter 9).

Suboptimal Facial Aesthetics after Orthognathic Surgery

An accurate pretreatment facial analysis should limit the incidence of suboptimal aesthetics after surgery. Many of the aesthetic treatment planning pitfalls for the correction of skeletal Class III patterns were reviewed earlier in this chapter. Clearly stated and realistic objectives that are discussed and agreed upon by all parties are essential. Comprehensive and meticulous treatment planning, accurate surgical execution, and good patient cooperation further ensure a favorable result. Despite the following of these steps, patient and family dissatisfaction are to be expected in a small percentage of cases.[40,41,56,68,103,115] Maintaining open lines of communication, reasonable patient and family flexibility, and clinician responsiveness to ongoing needs and concerns will generally result in the satisfactory resolution of these issues (see Chapter 7).

*References 19, 34, 35, 43, 45, 55, 59-61, 67, 69, 79, 80, 82, 96, 100-102, 107, 108, 111, 116, 118

Conclusions

When evaluating the developmental dentofacial deformity of *maxillary deficiency in combination with relative mandibular excess,* attention to both the skeletal anomalies and the soft-tissue envelope distortions is essential. The orthodontist's immediate goal in preparation for jaw reconstruction is to remove all dental compensations and to place the teeth solidly in the alveolar process. If extractions are required to uncrowd the alveolar arch and to ensure the patient's periodontal health, so be it. The surgeon will then reposition the jaws to establish a functional occlusion, an improved upper airway, and enhanced facial aesthetics.

A Le Fort I advancement (beyond cephalometric norms) with vertical adjustment and clockwise rotation in combination with mandibular ramus osteotomies and chin reshaping is the key to the achievement of favorable maxillofacial convexity, A-point to B-point relationships, and enhanced aesthetics in most patients. As a result, the soft-tissue envelope is stretched; this results in the loss of unattractive skin folds and distortions as well as the lessening of the deep creases that would otherwise occur with age.

- Conclusions

The prevalence of a *long face growth pattern* at a prominent U.S. maxillofacial center was documented as representing 22% of jaw deformity evaluations as judged from the parameter of excessive anterior facial height.[114] The lower anterior facial height was specifically long in 88% of the affected individuals.[54,74,75] The term *long face* is generally used to describe a maxillofacial growth pattern that typically also includes a gummy smile, an anterior open bite, and a lack of chin prominence. This combination of problems seems to be harder for the individual to live with; it results in a personal and family decision to seek treatment more frequently than most other patterns of dentofacial deformity (e.g., mandibular deficiency alone).[112] Halfway around the world, in South Africa, Reyneke estimated that, in his orthognathic practice, approximately 30% of those seeking treatment have a long face with complaints about a gummy smile and concerns caused by malocclusion.[117]

The basic diagnostic criteria for a long face growth pattern include an excessive anterior facial height (i.e., the elongation of the lower third) that leads to disproportion between facial height and width.[26,28,69,70] Studies confirm that the excessive eruption of the posterior maxillary dentition causes the mandible to rotate downward and backward (clockwise rotation) and results in increased lower facial height.[24,34] This makes any baseline mandibular anteroposterior deficiency seem worse and any true mandibular prognathism seem better.[31,123] As the mandible rotates down and back during facial development, the lower incisors often adapt by becoming more upright, with crowding. The mandibular clockwise rotation tends to separate the upper and lower incisors vertically, thereby creating an open bite with an accentuated curve of Spee.[76] Not all long face growth patterns involve an anterior open bite. The maxillary incisors also supra-erupt.[111,139] The anterior bite may stay closed or even become deep, depending on the extent of maxillary and mandibular incisor supra-eruption.[5,23,71,93-97,133] Whether the incisor relationship remains deep, normal, or open, lip incompetence (i.e., ≥4 mm of lip separation at rest) occurs, with mentalis strain that results from attempts to achieve lip closure.[27,99,100]

Functional Aspects

- Wide lip separation occurs, with excessive effort required during attempts to achieve lip seal.
- Chronic obstructive nasal breathing as a result of increased intranasal airway resistance (e.g., septal

deviation, enlarged inferior turbinates, tight nasal aperture, elevated nasal floor) is frequent (see Chapter 10).
- Classic articulation errors in speech as a result of the anterior open bite and lip incompetence are expected (see Chapter 8).
- Chewing and swallowing difficulties caused by the anterior open-bite malocclusion are expected (see Chapter 8).
- Detrimental effects on the dentition and the periodontium as a result of long-term traumatic malocclusion, the displacement of the teeth outside of the alveolar bone housing, or previous camouflage orthodontic and restorative treatments may be seen.
- The incidence of temporomandibular disorder may be higher than it is among individuals with normal jaw harmony and occlusion (see Chapter 9).

Clinical Characteristics

- Excessive anterior facial height, primarily in the lower third of the face
- Lip incompetence (i.e., resting lip separation of ≥4 mm)
- Increased exposure of the gingiva with a broad smile (i.e., a gummy smile)
- Increased frequency of anterior open bite (although one third of patients present with a normal or deep bite and only 15% have an open bit of >4 mm)
- Mandibular deficiency with Class II malocclusion is frequent (this can range from Class I to Class III)
- A mandible that is rotated downward and backward (i.e., clockwise rotation)
- An excessively full, curled lower lip when in a relaxed position
- Increased vermillion exposure of the lower lip
- A constricted or narrow alar base width, with depressed paranasal regions
- The appearance of a flat or sunken midface, without aesthetically pleasing facial curves or contours
- A negative vector relationship of the ocular globe to the lower eyelid

Dental Findings

- Anterior open bite (may be normal or deep)
- Excessive alveolar height in the anterior maxillary region (this will raise the floor of the nose and partially obstruct nasal airflow)
- Mandibular incisors that are upright, with crowding
- Accentuated curve of Spee as a result of the overeruption of the mandibular incisors
- Tendency toward a narrow, V-shaped maxillary arch with posterior crossbites (this is seen in approximately 50% of patients)
- Occlusal surface enamel wear on the posterior teeth as a result of grinding (secondary occlusal trauma) or previous occlusal equilibration performed in an attempt to close the anterior open bite

Radiographic Findings

- Excessive eruption of the maxillary posterior teeth (i.e., the distance from the palatal plane to the cusps of the molars)
- Maxillary horizontal deficiency
- Clockwise rotation of the maxilla (i.e., an increased palatal plane angle)
- Increased lower anterior facial height
- Clockwise rotation of the mandible (i.e., an increased mandibular plane angle)
- Normal or short mandibular ramus height
- Mandibular posterior teeth not excessively erupted
- Excessive eruption of the maxillary and mandibular incisors: with enough anterior hypereruption, a normal or deep overbite is more likely
- Measurable excessive eruption of the maxillary incisors (i.e., the distance from the floor of the nose to the incisal edge)
- Measurable excessive eruption of the mandibular incisors (i.e., the distance from the menton to the incisal edge)

Fields and colleagues presented simplified cephalometric diagnostic criteria.[44] If a patient has all three of the following criteria, he or she can be considered to have a long face growth pattern:

1. An increased mandibular plane angle
2. An increased total anterior facial height
3. A decreased percentage of upper to lower facial height

Etiologic Considerations

Current thinking is that both environmental influences and inherited tendencies play a role in the development of a long face.[53,66,67,85-87] A significant percentage of patients with long faces have been found to have an increased oral and decreased nasal breathing pattern.[25,33,37,52,59,82,134,146,150] Interestingly, nasal obstruction is not always present with long face growth patterns, but an open-mouth posture during development is typical. Other causes of an open-mouth posture in the preadolescent patient have been shown to result in similar long face dysmorphology.[1,2,4,51,61,78,80,140] This includes muscle weakness syndromes (e.g., Moebius syndrome, facial nerve palsy, cerebral palsy, muscular dystrophy) and the presence of a large tongue (e.g., Beckwith-Wiedemann syndrome, hemangioma, vascular malformations, neurofibromatosis, Proteus syndrome; see Chapter 4).

There is experimental animal model research to support the theory that a long face anterior open-bite malocclusion is a physiologic adaptation to an open-mouth protrusive tongue posture that is present during facial development (see Chapters 4 and 10).[62-65] It has also been clarified that, in humans, a resting open-mouth protrusive tongue posture is an etiologic factor in the development of a long face with an anterior open bite. Interestingly, the intermittent occurrence of tongue thrust during speech and swallowing is not

thought to be the cause of an open bite. In fact, periodic tongue thrusting is an adaptive response to an open bite rather than the cause.[47] When the incisors overlap in an average way (i.e., with a normal overbite), the normal-sized tongue is naturally placed behind the teeth to create the necessary anterior seal for successful swallowing and the articulation of specific consonant sounds (see Chapter 8). In the presence of anterior open bite, the normal tongue must protrude past the teeth to seal against the lips. This is an expected adaptive mechanism to assist with swallowing and speech. Confirmation that the protrusive tongue position during swallowing and speech is a reversible adaptation has been routinely documented after the individual with a long face and an anterior open bite undergoes successful orthognathic surgery and orthodontic treatment.[89,142,155] When the open bite is closed with the use of sound biologic mechanics (i.e., without orthodontic dental compensation) and when lip competence is achieved through surgery (i.e., there is no longer excess lower facial height), there is a fairly reliable elimination of the tongue thrust without the need for active myofunctional physical therapy retraining. However, if a skeletal anterior open bite has been closed with the use of unsound orthodontic maneuvers (i.e., excessive eruption of the anterior teeth or buccal tipping of the molars outside of the alveolar bone housing) and if lip competence is not achieved (i.e., inadequate facial height shortening), dental relapse is to be expected. In this case, tongue thrusting should not be blamed for the recurrent malocclusion.

The Role of Growth Modification in the Preadolescent Patient

When standard growth modification maneuvers for a long face growth pattern are attempted in the preadolescent patient, the primary objective is to restrain the hypereruption of the posterior maxillary teeth. In theory, this would limit the abnormal downward and backward rotation of the mandible. Unfortunately, effective and practical methods for accomplishing this seemingly limited objective have been difficult to orchestrate. It has also been shown that the natural progression of the deformity may persist through adolescence. This means that the effective containment of the maxillary posterior dental hypereruption would need to continue throughout the teenage years. The two traditional methods that are used to impede excessive vertical growth of the posterior maxilla are 1) the use of *high-pull headgear* connected to a complete or partial maxillary fixed appliance and 2) the use of a *functional intra-oral appliance* that incorporates a bite-block device (i.e., an activator) between the teeth.

The intraoral functional appliance is usually designed to exert force on the posterior teeth when the masticatory muscles contract. The occlusal force is then transferred through the biting surfaces of the upper and lower posterior teeth to the periodontal ligaments to limit molar eruption. To be effective, most clinicians recommend that the functional appliance be worn for 14 to 16 hours per day. When headgear is used, it is designed to apply direct external force to the teeth through a fixed maxillary appliance. Unfortunately, true vertical pull is almost impossible to achieve, and this results in a degree of added backward pressure. Because the majority of patients with long faces do not have protrusion of the maxilla, this unavoidable posterior force is counterproductive and results in further horizontal maxillary deficiency. The combination of vertical intrusion vectored headgear and an intra-oral functional appliance to affect the posterior dentition—when initiated during childhood and sustained through the teenage years in a compliant child—is thought to have the potential to produce improvement in the patient with a long face growth pattern. In all but borderline long faces, which are recognized during childhood, growth modification is not likely the preferred approach.

The Orthodontic Camouflage Approach

The patient with a long face often perceives a visual prominence of his or her upper incisors. For this reason, it is apparently tempting for the orthodontist to proceed with a camouflage treatment plan to neutralize the occlusion via the retraction of the upper incisors. This approach seems to be especially difficult for the orthodontist to avoid when viewing the problem primarily as a Class II malocclusion without fully considering the vertical and horizontal skeletal disharmony, the lip incompetence, the upper airway dysfunction, and the overall facial aesthetics. The extraction of the maxillary first premolars followed by the retraction of the anterior teeth will improve and may even neutralize the occlusion, but it does nothing to relieve the vertical facial problem, and it will further accentuate the horizontal facial deficiency. As the incisors are orthodontically retracted, they are also elongated (i.e., extruded), and the nasolabial angle opens, which results in unattractive effects on the lips and the nose.

Before embarking on an orthodontic camouflage approach, the clinician should confirm that the patient and his or her family understand the aesthetic limitations of closing the anterior open bite by extruding the incisors (i.e., residual or worsening gummy smile, residual lip incompetence with mentalis strain, lack of facial aesthetic improvement). The patient's long-term dental stability and periodontal health must also be considered. In addition, the maxilla, the mandible, and the chin will remain horizontally deficient and vertically long, thereby further accentuating lip incompetence and the long, flat, retrusive appearance of the profile.

An Orthodontic Molar Intrusion Approach

Sato and colleagues believe high-angle Class II malocclusions can be corrected with the use of "multiloop edgewise

arch wires."[124] With the use of tip-back mechanics and vertical elastics, the researchers believe that the occlusal plane inclination can be altered by intruding the molars via the autorotation of the mandible and the closure of the open bite. Unfortunately, scientific evidence in support of this method of treatment for a patient with a long face and an anterior open bite has not been forthcoming.

With the use of skeletal temporary anchorage devices, the intrusion of the molars has been recommended by some to close an open bite.[105,157,158] Man-Suk and colleagues completed a study to examine the long-term stability of anterior open-bite correction via the intrusion of the maxillary posterior teeth in adults.[88] In the first group (n = 5 adults), mini-screw implants were placed on the buccal and palatal sides, between the roots of the maxillary second premolars and first molars and between the roots of the maxillary first and second molars. Intrusion forces were directly applied to the molars with elastomeric chains. In the second group (n = 4 adults), mini-screw implants were placed on the buccal side only between the roots of the maxillary second premolars and first molars and between the roots of the maxillary first and second molars. A rigid transpalatal arch was placed before applying the intrusive forces to prevent the buccal tipping of the teeth. Lateral cephalograms were taken at the initial evaluation and again at 1 and 3 years after treatment. The cephalograms were traced and analyzed. The study documented that the maxillary first molars were intruded on an average of 2.39 mm during treatment, with relapse of 0.45 mm at the 3-year follow up (i.e., 22.9% relapse). A majority of the relapse occurred during the initial posttreatment year. The molar relapse had a significant effect on the eventual incisal overbite. There was no significant difference in molar relapse or the maintenance of overbite between the two different methods of skeletal anchorage used. It would appear as though there is currently no known way to fully retain an orthodontically intruded molar.

For patients with borderline long face growth patterns in whom the open bite has been successfully closed with the use of orthodontic mechanics and in whom the remaining gummy smile and lip incompetence is only mild, a vertical reduction with horizontal advancement genioplasty may improve the profile aesthetics and lip competence enough to be a satisfactory compromise for the patient (see Chapter 37 and 40).

Definitive Reconstruction

Timing of Orthognathic Surgery

Orthodontic or surgical interventions undertaken in the individual with a long face growth pattern will not be definitive if significant jaw growth continues after treatment. In our experience, when the increased intranasal airway resistance is simultaneously managed as part of the definitive jaw reconstruction, excessive ongoing vertical growth ceases.[108,110] Even if minor degrees of vertical growth were to continue, it should occur in both the mandible and the maxilla in a proportionate way.

If the individual with a long face is either a normal mandibular grower (i.e. Class I) or a mandibular-deficient grower (i.e. Class II), then after he or she is in the permanent dentition and the teeth are orthodontically aligned, ongoing horizontal jaw growth after reconstruction is unlikely.

Horizontal jaw growth maturation may be analyzed with the use of serial lateral cephalometric radiographs. These sequential radiographs can be used to make direct mandibular measurements. Surgery is delayed until the deceleration of growth can be documented. The best evidence available indicates that, when orthognathic surgery is undertaken in the mandibular-deficient patient as early as completion of the adolescent growth spurt, forward growth of the mandible almost never occurs.[135] Further horizontal growth of the maxilla at this age is also not expected.

For all of these reasons, proceeding with definitive orthognathic and intranasal surgery for the patient with a Class II long face growth pattern when he or she is as young as 14 years old is generally safe from a growth perspective, but only after the eruption and orthodontic alignment of the teeth (Fig. 21-4).

Preorthodontic Periodontal Considerations

Assessing the individuals biologic and anatomic risk factors for periodontal injury should be undertaken before starting orthodontic treatment.

Orthodontic attempts to compensate the occlusion in the patient with a long face growth pattern may result in gingival recession along the labial aspect of the lower incisors and the buccal aspect of the posterior maxillary teeth. The advantage of bicuspid extractions in the mandible or the maxilla should always be considered to achieve full positioning of the dental roots solidly in the alveolar bone (see Chapter 6).

When lip competence and an improved nasal airway have been achieved as a result of jaw and intranasal procedures, the dryness of the gingiva (ex. inflammation) will also diminish (see Chapter 6).

Orthodontic Preparation for Orthognathic Surgery

The orthodontic mechanics should be oriented toward positioning of the teeth solidly in the alveolar housing within each arch and specifically within each maxillary segment as indicated.[128,132,145,149,151] A goal is for the teeth to occlude together appropriately at the time of surgery and after finishing orthodontics. The preferred and anticipated occlusion is best confirmed via the periodic review of dental models (see Chapter 5).

From the beginning, the orthodontist and the surgeon make joint decisions concerning the treatment approach. One aspect that they will consider is whether the maxilla is

to remain in one piece or to be segmented; if segmentation is planned, they will determine at what locations this will occur. The decision for or against segmentation of the maxilla is driven by the baseline skeletal deformity and not for reasons of clinical expedience. A patient with a long face and a moderate or severe anterior open bite will generally have an excessive curve of Spee in the upper arch. Vertical steps in the maxillary arch exist that are coincident with the degree of dentoalveolar dysplasia. The more severe the vertical alveolar and dental step-offs, the more exaggerated the curve of Spee and the more obvious the need for segmental orthodontic mechanics and segmental surgical repositioning as part of the overall correction.

With maxillary surgical segmentation planned, the orthodontist's presurgical goal is to level the teeth independently within each segment. With a decision made to also defer arch expansion to the surgical phase (i.e., segmental osteotomies with widening), the orthodontic alignment of the teeth within each segment becomes the preoperative objective. Furthermore, there is no need or advantage for the orthodontist to create a space at the planned interdental osteotomy sites (i.e., between the lateral incisor and canine on each side or between the central incisors), because the roots are naturally divergent (see Chapter 17). The orthodontic preparation before surgery should incorporate the following basic concepts:

1. *The mandibular arch is leveled with the use of standard orthodontic mechanics before surgery.* A patient with a long face does not generally have a severely exaggerated curve of Spee in the lower arch. Therefore, complete leveling is generally carried out before surgery (with or without the need for extractions).
2. *The presence of an excessive reverse curve of Spee in the maxillary arch is an indication of a skeletal problem rather than a dental one.* Orthodontic leveling of the arch in segments (i.e., four incisors, the canine through the second molar on the left side, and the canine through the second molar on the right side) is generally consistent with the skeletal dysmorphology, and it is carried out before surgery. With the curve of Spee orthodontically leveled in each of the three components, segmental Le Fort I osteotomies will allow for the placement of the three individually leveled components over the orthodontically leveled mandibular arch to achieve the preferred occlusion at operation.
3. *The presence of a narrow maxilla is an indication of skeletal dysplasia rather than dental malposition*. Orthodontic tooth movement should remain consistent with the narrow skeletal width. Each posterior segment (i.e., the canine through the second molar on the left side and the canine through the second molar on the right side) should be independently orthodontically leveled. Segmentation of the downfractured maxilla will then adjust the arch width to the orthodontically leveled mandibular arch. If the posterior teeth have not been orthodontically positioned fully within the alveolar housing (e.g., if there is buccal tipping of molars), dental relapse after surgery with a return of the narrow maxillary arch width and the open-bite malocclusion is more likely to occur (see Chapter 17).

Basic Mandibular Arch Mechanics

- Routine orthodontic mechanics are used to level, align, close up spaces, and achieve appropriate arch form in the lower jaw.
- Extraction of a bicuspid in each quadrant (or of a single incisor, in rare cases) or interproximal reduction may be needed in the lower arch to uncrowd the dental crowns, to set the roots solidly in the alveolar housing, and to correct incisor inclination.

Basic Maxillary Arch Mechanics

- In the presence of vertical skeletal discrepancies, presurgical orthodontic stabilization may be achieved with sectional finishing wires that conform to the arch shape of each segment.
- If no vertical segmental skeletal discrepancies exist, then the maxillary arch is leveled with a continuous arch wire. Care is taken to prevent the forward flaring of the incisors. Posterior intrusion mechanics are also avoided, because they predispose the patient to late dental relapse.
- The advantage of bicuspid extractions to position the remaining roots solidly in alveolar housing should always be considered.
- In our experience, planning the interdental osteotomies between the canines and the first bicuspids is rarely preferred. Segmentation in this location is technically more time-consuming for the orthodontist (i.e., precise intercanine width orthodontic detailing becomes necessary), and it is more prone to dental injury and periodontal sequelae (i.e., pocketing and gingival recession) from the interdental osteotomy at surgery.
- Segmentation between the lateral incisors and the canines is generally preferred. When segmenting in this location, it is not necessary or advantageous for the orthodontist to create space at the planned osteotomy sites, because the roots are naturally divergent. The advantages of segmenting the maxilla in this location (i.e., between the lateral incisor and the canine) on each side and then parasagittally (i.e., down the hard palate) include the simplification of orthodontic mechanics, the prevention of periodontal sequelae, and the ability to positively influence incisor inclination without negatively affecting the vertical facial height.

Basic Surgical Approach

The surgical approach for the treatment of a classic long face is best carried out through a combination of osteotomies, including Le Fort I osteotomy in segments, bilateral sagittal split ramus osteotomies, and oblique osteotomy of the

chin (Figs. 21-1 through 21-10).* Management of the anterior neck soft tissues—including cervical soft-tissue flap elevation, neck defatting, and vertical platysmal muscle plication—can also be carried out, if desired (see Chapter 40). The removal of the impacted wisdom teeth is frequently recommended for long-term dental health. If this is planned, it can be accomplished at the same time (see Chapters 15 and 16).

If septoplasty, inferior turbinate reductions, or both are required to improve nasal airflow, then the procedures are carried out simultaneously (see Chapter 10).[108-110] For the patient with a long face growth pattern, an important aspect of nasal aesthetics and airway management is to also simultaneously lower and recontour the floor of the nose, the pyriform rims, and the anterior nasal spine region. In 1985, Ellis used lateral cephalometric radiographs to study the specific regions of vertical maxillary excess in mature individuals (i.e., >17 years old) with long faces.[36] In the study patients, the linear distance between the incisal edge and the floor of the nose (i.e., the upper incisal edge to the anterior nasal spine) was found to be significantly increased. In other words, the anterior floor of the nose was excessively high, which at least partially accounted for the diminished nasal aperture opening. Ellis recognized that, when a standard Le Fort I maxillary intrusion is carried out to decrease the gummy smile, the elimination of any excessive alveolar bone in the area of the pyriform fossa should also be considered. In these cases, I recommend that the floor of the nose and the anterior nasal spine regions be recontoured to lower the floor. When this is done, the nasal airway is improved, and the "bunching" of the nasal and paranasal soft tissues is avoided. I agree with Ellis and Westermark that the popular use of an alar cinch stitch is generally carried out as a soft-tissue attempt to solve a skeletal problem.[36,154] Although the alar cinch stitch will have effects on the nasal base width, it will also have secondary effects on the nasolabial angle and the nasal tip projection that may not be positive.[118] In addition, if the cinch stitch is completed without fully correcting the skeletal aspects (i.e., lowering the nasal floor and recontouring the anterior nasal spine), suboptimal nasal aesthetics and further airway obstruction are likely.[55,92,144]

One of the indications for the segmenting of the maxilla is to correct transverse dental width deficiencies.[7,9,10,22,56,77,79,129,130] In the past, problems of stability with transverse expansion have led some clinicians to recommend a two-stage surgical approach to maxillary reconstruction for a long face growth pattern. The first stage involves surgically assisted rapid palatal expansion to widen the maxilla during the presurgical orthodontic phase of treatment. Approximately 6 to 18 months later, a Le Fort I down-fracture osteotomy is carried out as part of the definitive orthognathic correction to reposition the maxilla vertically and horizontally, as indicated. As discussed in Chapter 17, I recommend a single-stage orthognathic approach in most cases. This includes a Le Fort I down-fracture osteotomy with segmentation to simultaneously correct the curve of Spee; any transverse discrepancy; vertical dysplasia; horizontal dysplasia; canting (i.e., roll orientation); any midline discrepancies (i.e. yaw orientation); and A-point to B-point discrepancies (i.e., pitch orientation).

NOTE: The literature does not confirm a better outcome with a two-stage surgical approach to maxillary deficiency in individuals with long faces.[30] The potential for increased morbidity as well as the increased time and financial costs of a two-stage surgical approach cannot be justified in most cases (see Chapter 17).

Immediate Presurgical Planning

The immediate presurgical planning takes into account collaborative clinical efforts among the orthodontist, the surgeon, the patient, and the family that will have been ongoing since the initial consultation visits.* Depending on the condition of the dentition and the supporting structures, the restorative dentist and the periodontist may also have been intricately involved.

The patient's specific medical and dental records are reviewed, including radiographs (e.g. computed tomography scans; panoramic, lateral, and posteroanterior cephalometric images and periapical radiographs); facial and occlusal photographs; and dental models. Immediate presurgical records (i.e., within 2 to 6 weeks of surgery) will most importantly include facial measurements taken during a direct visual examination of the patient; alginate impressions of the maxilla and the mandible; centric relation bite recording; and face-bow registration.

First, broad-stroke decisions are made regarding the preferred vector changes for each jaw; only then are the precise millimeter distances and angular changes required in each jaw to achieve the desired end result determined (see Chapter 12). Analytic model planning is carried out on the articulated dental casts with use of the Erickson Model Table. Splints are constructed to assist with the achievement of the precise occlusion and preferred facial aesthetics in the operating room (see Chapters 13 and 14).

The basic vector changes required in the maxilla to correct a long face growth pattern frequently include maxillary horizontal advancement; the shortening of the anterior (vertical) height; transverse widening; and the correction of the curve of Spee to match the mandibular arch. Basic vector changes often incorporate counterclockwise rotation of the maxillary plane (i.e., pitch orientation) as needed to achieve a preferred A-point to B-point

• **Figure 21-7** A high-school girl arrived with her parents for evaluation. She refused an orthognathic approach at the time but then returned during her college years to request correction. Her history and physical examination confirmed nasal obstruction, lip incompetence, and difficulty chewing. The facial aesthetic concerns included an awareness of a weak chin, a gummy smile, lip strain, and the impression of having a larger nose. The patient had been under an orthodontist's care since the mixed dentition. Rapid palatal expansion and full bracketing with attempted closure of the anterior open bite were not successful. Further evaluations were carried out by a speech pathologist and an otolaryngologist, and a fresh look was taken at the patient's orthodontic needs. Orthodontic decompensation that included four bicuspid extractions in combination with orthognathic and intranasal surgery was chosen. The simultaneous procedures carried out included Le Fort I osteotomy in segments (horizontal advancement, vertical shortening, and arch expansion); sagittal split ramus osteotomies (horizontal advancement); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 21-9** A young woman arrived for surgical evaluation. Her history and physical examination confirmed lifelong nasal obstruction, lip incompetence, difficulty chewing, and frequent speech articulation errors. The facial aesthetic concerns included an awareness of a weak chin, a gummy smile, lip strain, and the impression of having a larger nose. The patient had experienced secondary occlusal trauma with a need for root canal therapy and crowns on multiple posterior teeth. Further investigations were carried out by a speech pathologist and an otolaryngologist, and a fresh look was taken at the patient's requirements for the achievement of a satisfactory occlusion. Orthodontic decompensation including four bicuspid extractions in combination with orthognathic and intranasal surgery was chosen. The simultaneous procedures carried out included Le Fort I osteotomy (horizontal advancement, vertical shortening, and counterclockwise rotation); sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 21-10** A 17-year-old boy arrived with his parents for surgical evaluation. His history and physical examination confirmed lifelong nasal obstruction, heavy snoring, difficulty chewing, and frequent speech articulation errors. The facial aesthetic concerns include an awareness of a gummy smile, lip strain, and a weak profile. Earlier during his life, he had undergone orthodontics that included rapid palatal expansion and full bracketing, without success. An anterior open bite and constricted arch-width malocclusion remained. Further evaluations were carried out by a speech pathologist and an otolaryngologist, and a fresh look was taken at the patient's orthodontic needs. Orthodontic decompensation in combination with orthognathic and intranasal surgery was chosen. The simultaneous procedures carried out included Le Fort I osteotomy in segments (horizontal advancement, vertical shortening, counterclockwise rotation, arch expansion, and the correction of the curve of Spee); sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

relationship and pogonion projection when viewing the patient's profile in the natural head position. The immediate presurgical models will confirm details of the planned segmentation of the maxilla and the need for any occlusal equilibration to achieve the preferred occlusion in the operating room.

Linear (millimeter) and angular (degree) decisions regarding the preferred repositioning of the maxilla specifically incorporate the following:

- The desired vertical positioning of the maxillary incisor crown
- The desired horizontal positioning of the maxillary incisor crown
- The need to reposition the maxillary dental midline to match the facial midline (i.e., yaw orientation)
- The need to alter or correct any maxillary cant (i.e., roll orientation)
- The need to vertically adjust the posterior maxillary height to establish a preferred A-point to B-point relationship of the jaws (i.e., pitch orientation); counterclockwise rotation of the maxillary plane is a frequent maneuver
- The need to or benefit of segmenting the maxilla to alter the arch width or the curve of Spee

Immediate presurgical planning will confirm the anticipated functional and aesthetic advantages of sagittal split ramus osteotomies to reposition the mandible into occlusion with the new maxillary position versus accepting the limitations of mandibular autorotation (i.e., one-jaw surgery). The baseline anterior projection of the maxilla in a patient with a long face is generally deficient and requires horizontal advancement at the level of the maxillary incisors. Horizontal advancement in combination with vertical intrusion and pyriform rim recontouring will limit the undesirable widening of the nose that would otherwise occur with a "straight-up" intrusion of the maxilla and autorotation of the mandible. *Simultaneous sagittal split ramus osteotomies of the mandible (i.e., two-jaw surgery) are required to achieve these objectives in almost all cases.*[118-121] It is also likely that an oblique osteotomy of the chin with vertical shortening and limited horizontal advancement will be advantageous.

The clinician should confirm or refute a lifelong history of chronic obstructive nasal breathing in the patient (see Chapter 10). During the physical examination, intranasal findings that are consistent with increased nasal airway resistance are likely to include septal deviations and inferior turbinate hypertrophy. If the history and physical findings warrant, then septoplasty and inferior turbinate reduction should be carried out to improve nasal breathing. The baseline presence of excess vertical height in the anterior maxilla (i.e., a high nasal floor) with lip incompetence and a constricted nasal width (i.e., a tight nasal aperture) is also typical and will benefit from midface intrusion, arch expansion through segmental osteotomies, and horizontal advancement. Recontouring of the nasal floor, the pyriform rims, and the anterior nasal spine region with a bur on a rotary drill is also an important surgical maneuver to achieve preferred upper lip and nasal aesthetics as well as to ensure maximum improvements in upper airway function (see Chapters 10 and 15).

These maxillary surgical maneuvers will also improve the negative vector ocular globe to lower eyelid relationship that was present preoperatively (see Chapter 25). In the teenager and young adult, this will stabilize the midface and periorbital soft tissues and limit the negative effects that would otherwise likely occur with age (e.g., soft-tissue descent, rounding of the palpebral fissure, lengthening of the lower lid, loss of cheek region soft-tissue prominence).

Surgical Planning Pitfalls

The Need for Two-Jaw Surgery

It is better to accept the need for bimaxillary and chin osteotomies in combination with intranasal procedures to obtain a favorable result rather than to compromise facial aesthetics and airway improvements in an attempt to keep the surgery within one jaw. For the patient with a long face, bimaxillary surgery is almost always beneficial to achieve the desired midface (maxillary) projection; to achieve the desired lower face (mandibular) projection; and to achieve the preferred profile line (i.e., via the control of A-point to B-point positioning through the use of counterclockwise rotation).

Maxillomandibular Counterclockwise Rotation

The achievement of a preferred A-point to B-point relationship (i.e., pitch orientation) when the patient is in the natural head position is essential for enhanced facial aesthetics. For a patient with a long face growth pattern, counterclockwise rotation of the mandibular plane is typically carried out. The maxillary plane may also require counterclockwise rotation with intrusion of the anterior maxilla (thus lessening the gummy smile) in combination with either neutral or, to a lesser extent, intrusion of the posterior maxilla. The achievement of an actual numerical plane angle is not in itself an objective. The maxillomandibular complex is counterclockwise rotated as needed to achieve the preferred profile aesthetics. Although it has been much discussed, the use of sagittal split ramus osteotomies of the mandible prevents the lengthening of the posterior facial height during these maneuvers. The proximal segment of the mandible (i.e., the condyle and ramus section) remains essentially neutral, regardless of clockwise or counterclockwise rotation of the distal aspect of the lower jaw.

Managing Incisor Inclination

When the maxillomandibular complex is counterclockwise rotated to improve the pitch orientation, effects on both the base of the nose and the relative maxillary incisor

inclination above and the pogonion and the relative mandibular incisor inclination below are to be expected. The extent of baseline deformities and the need for pitch orientation correction will influence the extent of recontouring required at the pyriform rims above and chin repositioning below to enhance facial aesthetics.

Treating the Gummy Smile

When considering the enhancement of the relationship of the upper lip to the maxillary upper incisors, it is important to avoid the planning pitfall of treating the gummy smile as an isolated feature. The clinician should make decisions about the degree of excessive anterior maxillary height and the extent of planned intrusion primarily on the basis of the anticipated upper lip position in repose and not on its position during a smile (see Fig. 21-8). In the patient with a long face, surgical alteration of the upper lip to tooth relationship will occur for a variety of reasons, including vertical maxillary intrusion; horizontal maxillary advancement; arch expansion; closure of the open bite; shortening of the chin; recontouring the pyriform rims; and recontouring and lowering of the nasal floor. The dynamic lip function and the static lip position after healing cannot be entirely predicted from the combination of skeletal changes that are generally carried out. No accurate quantitative mathematic formula for predicting the postoperative hard tissue to soft tissue changes with this condition is currently available. Keep in mind that as much as 4 mm of incisor crown exposure at rest is fine; a few millimeters of lip incompetence is acceptable, and it is better to show more teeth than less.

Postsurgical Orthodontic Maintenance and Maintenance

In general, the maintenance of the new arch form is the most challenging aspect of the postsurgical orthodontic phase of treatment. With segmentation of the maxilla, a rigid acrylic occlusal splint is prefabricated and secured to the maxillary dentition in the operating room (see Chapter 13). The splint remains in place during the initial bone-healing phase, (approximately 5 weeks). Intermittent intermaxillary elastics are used during this time to retrain the masticatory muscles, to provide motion in the temporomandibular joints, to increase patient comfort, and to confirm the stability of the occlusion. When the splint is removed, the patient should immediately (ideally within 24 hours) return to the orthodontist for the placement of a continuous maxillary arch wire. The surgically expanded arch width and the corrected curve of Spee must be actively orthodontically maintained throughout occlusal finishing (see Chapter 17). In accordance with the orthodontist's clinical judgment, this is accomplished via some combination of a rigid labial wire, a transpalatal appliance, and a palatal acrylic plate. The placement of a transpalatal appliance at the time of splint removal is facilitated by preoperatively banding the first molars with lingual attachments. The transpalatal appliance can be constructed in advance from the maxillary cast of the model planning. It is often tempting for the orthodontist to rapidly finish treatment and remove the brackets, but this is almost always a mistake. The dentoalveolar segments are generally not fully stable for approximately 6 months. If the maxillary posterior segments relapse after surgery, not only will there be a return of posterior crossbites, but the occlusion also tends to open anteriorly (see Chapter 16).

Complications, Informed Consent, and Patient Education

The orthodontist and the surgeon are asked to evaluate the individual with a long face and then to attempt to alter nature's events. With a sound understanding of the natural progression of the uncorrected dentofacial deformity and with knowledge of how specific interventions will affect function and facial aesthetics, predictable results are generally expected. The potential risks as compared with the anticipated benefits of each procedure and the review of alternative approaches to manage each problem are taken into account, because complications (i.e., unfavorable outcomes) will always occur in a small percentage of patients. The patient's willingness to make an informed decision and then to accept responsibility for that choice is an integral aspect of the patient–doctor interaction (see Chapter 17).[115]

Malocclusion after Orthodontics and Orthognathic Surgery

There are inherent biologic challenges to the orthodontic movement of the teeth within the alveolar process and the surgical repositioning of the jaws and jaw segments in the individual with a long face.* This includes the technical aspects of the repositioning; the initial healing requirements; and the difficulties associated with the long-term maintenance of the mechanically relocated teeth, jaws, and jaw segments. When following sound aesthetic and biomechanical principles, clinicians are able to carry out orthodontic treatment and surgical procedures in the individual with a long face to safely and reliably achieve the desired results in most cases. Potential intraoperative technical difficulties associated with sagittal split ramus osteotomies of the mandible and the maxillary Le Fort I osteotomy that can result in an immediate (early) malocclusion are preventable in most cases (see Chapter 17). Timing the surgical procedures to limit the risk of ongoing jaw growth after surgery is generally possible. The orthodontic removal of dental compensations with the use of bicuspid extractions as needed to place the teeth solidly in the alveolar housing

*References 8, 35, 42, 45, 49, 50, 81, 90, 91, 104, 106, 113, 126, 131, 136, 137

will best ensure stable long-term occlusion and periodontal health (see Chapter 17).

Temporomandibular Disorders: Effects of Orthodontics and Orthognathic Surgery

It is estimated that an average of 32% of the population reports at least one symptom of temporomandibular disorder, whereas an average of 55% demonstrate at least one clinical sign. Temporomandibular disorders include various symptoms and signs of the temporomandibular joints, the masticatory muscles, and the related structures. The symptoms and signs may include a spectrum of referred head and neck discomforts; joint noise (e.g., popping, clicking, crepitus); reduced or altered mandibular movements as a result of muscle spasm or disc displacement, with or without reduction; condylar head erosion; and pain on direct palpation of either temporomandibular joint or of the masticatory muscles. The presence of an anterior open-bite malocclusion is often claimed to be a factor in temporomandibular disorder. The successful correction of the Long Face dentofacial deformity through orthodontics and orthognathic surgery has been documented to improve the pretreatment symptoms of many individuals, but it may accentuate symptoms in others (see Chapter 9).[3,103]

Conclusions

The *long face growth pattern* represents a frequent presentation of dentofacial deformity for which many individuals request treatment. The opportunities for the treating clinicians to effectively improve the presenting head and neck dysfunctions (e.g., mastication, speech articulation, swallowing, breathing, lip closure/posture) and also to achieve enhanced facial aesthetics are significant. A coordinated approach and a well-informed patient and family generally result in orthodontic and surgical treatment being a life-changing event.

- Conclusions

A specific pattern of dentofacial deformity that occurs after birth and that primarily affects the mandible may be referred to as an *asymmetric mandibular excess growth anomaly.** This is a useful term for name recognition, but it falls short of explaining the causes and effects of this common pattern of jaw deformity. This condition typically results in an uneven Angle Class III malocclusion, and it has been referred to by a variety of terms, including *deviated mandibular prognathism, condylar hyperplasia, mandibular lateral gnathism, osteochondroma of the mandibular condyle,* and *asymmetric Class III dentofacial deformity.* The overall effect on maxillofacial morphology also includes the secondary deformities that occur to the maxilla, the nose, the chin region, the position of the teeth, and the distortions that are visually observed in the overlying soft-tissue envelope. These effects are dependent on multiple factors, including the intensity of the mandibular hyperactivity; the patient's age when the abnormal bone growth begins; any underlying hereditary dentofacial deformity tendency; and the treatment that was previously rendered (i.e., orthodontic, dental, or surgical) before the patient's arrival to the surgeon for evaluation. These *asymmetric mandibular excess growth patterns* may be confused with other causes of maxillomandibular asymmetry (i.e., hemifacial hyperplasia, hemifacial microsomia, growth disturbance after a condyle injury during childhood).[10,27,48,49,55,93,94,124] Most misdiagnosis are easily clarified by taking an accurate history, completing a physical examination, and reviewing the patient's radiographs (Fig. 22-1).

Obwegeser believes that this dentofacial deformity is caused by two different growth regulators.[23-25,68-91] The first is a more rare form, and it is clinically characterized by an increase in volume of all parts of the affected side of the mandible, without a lateral shift of the chin to the opposite side. Its primary effects end near the midline at the symphysis (Figs. 22-2 through 22-5). The second and more common form of this dentofacial deformity is characterized by an elongation of the affected side of the mandible, often with widening of the gonial angle and with clear displacement (i.e. lateral shift) of the midline of the chin and the mandibular dental midline to the opposite side of the face (Figs. 22-6 through 22-14).

Obwegeser also stated that these two pure forms of dentofacial deformity may present as a spectrum.[23-25,68-91] He called these two pure dentofacial deformities *Type I* or *hemimandibular hyperplasia* and *Type II* or *hemimandibular elongation.* Obwegeser hypothesized that the steering mechanism for the growth of these two distinct mandibular anomalies is located entirely within the cartilaginous zone of the condylar head. This was proven to him by the fact that, whenever a very rapidly developing mandibular overgrowth (either Type I or Type II) was encountered, he was able to arrest the growth and prevent further deformity by completing a high condylar resection.

Text continued on p. 853

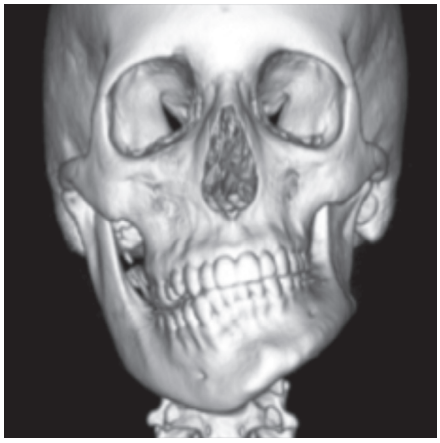
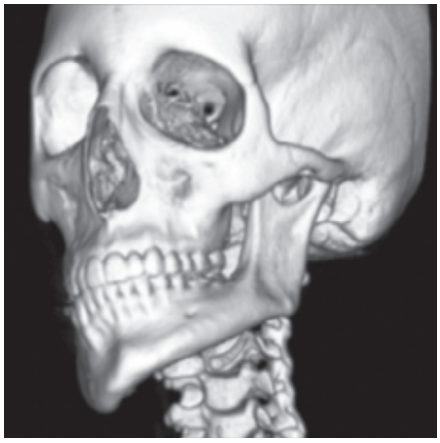
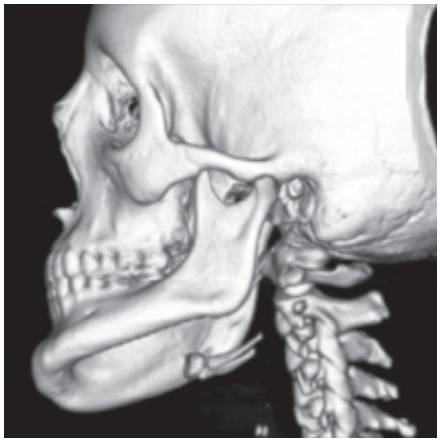
• **Figure 22-1** Asymmetric mandibular excess growth patterns are often confused with other causes of maxillomandibular asymmetry. Most misdiagnoses are easily clarified by taking an accurate patient history, completing a physical examination, and reviewing the patient's radiographs. **A,** A teenage girl with hemifacial hyperplasia of the right side is shown. This anomaly involves the overgrowth of both the soft and hard tissues on one side of the face. There is an asymmetric Class III malocclusion with a shift of the mandibular dental midline to the opposite side. **B,** Hemifacial microsomia results in the deficiency of tissues within the first and second brachial arches on one side of the face. The intraoral examination is usually consistent with an asymmetric Class II excess overjet malocclusion. This 15-year-old girl with hemifacial microsomia of the right side demonstrates these findings. There is a shift of the mandibular dental midline toward the ipsilateral side. **C,** A 12-year-old boy in the permanent dentition sustained a right condyle fracture of the mandible earlier during his life with resulting ipsilateral (right side) mandibular hypoplasia and secondary deformities of the maxilla. He presented with an asymmetric Class II deepbite malocclusion. There is a shift of the mandibular dental midline toward the ipsilateral side. The overlying soft-tissue envelope is distorted but not malformed.







• **Figure 22-2** A teenage girl with right side hemimandibular hyperplasia. She demonstrates a typical phenotype as described within the chapter. **A,** Frontal facial and computed tomography (CT) scan views without intervention. **B,** Left facial oblique and CT scan views without intervention. **C,** Left profile and CT scan views without intervention.

• **Figure 22-5** A 17-year-old female with hemimandibular hyperplasia of the left side and the typical facial and occlusal phenotype. She also has a lifelong history of obstructed nasal breathing. She underwent a comprehensive orthodontic and orthognathic surgical approach. Her procedures included maxillary Le Fort I osteotomy in segments (minimal advancement, cant correction, and arch expansion); bilateral sagittal split ramus osteotomies (cant correction and minimal horizontal advancement); left mandibular inferior border recontouring; osseous genioplasty (asymmetry correction); and septoplasty and inferior turbinate reduction. Note that asymmetry is present at the inferior borders before surgery and that there is much improvement afterward. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 22-6** This is a 15-year-old girl who had been evaluated for routine orthodontic care when she was 12½ years old. At that time, she had not yet begun her menses or undergone a pubertal growth spurt. Routine orthodontics were initiated. By the time she was 15 years old (i.e., 2 years after menarche and a pubertal growth spurt), she developed an obvious asymmetric mandibular excess growth pattern due to right condylar overgrowth (Type II Hemimandibular Elongation). This resulted in both facial asymmetry and an asymmetric Angle Class III negative overjet with a posterior crossbite malocclusion. The mandibular dental midline and chin are shifted to the contralateral side. **A,** Facial and occlusal views when the patient was 12 years old. **B,** Facial and occlusal views when the patient was 15 years old. **C,** Panorex radiographs when the patient was 12 and 15 years old, respectively.

• **Figure 22-7** A 17-year-old boy with a diagnosis of left hemimandibular elongation is shown. This condition affects his chewing and speech articulation. The patient has a lifelong history of the obstruction of his nasal breathing. During his early teenage years, the patient underwent an initial phase of orthodontics, without success. He was referred for surgical evaluation and then underwent a combined redo orthodontic and surgical approach. With the relief of dental compensation, the patient's surgery included maxillary Le Fort I osteotomy in segments (horizontal advancement, cant correction, arch expansion, and clockwise rotation); bilateral sagittal split ramus osteotomies (cant correction and mandibular straightening); septoplasty and inferior turbinate reduction; and osseous genioplasty (straightening). **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 22-7, cont'd** **C,** Oblique facial views before and after reconstruction. **D,** Profile views before and after reconstruction.

• **Figure 22-8** A 17-year-old male high school student was referred by his orthodontist for surgical evaluation. His asymmetric Class III negative overjet anterior open-bite malocclusion was consistent with hemimandibular elongation. He required redo orthodontics and jaw surgery with a non-extraction approach. The patient had a lifelong history of nasal obstruction and consistent physical findings, so intranasal procedures were also required. With orthodontic decompensation complete, the patient's surgery included maxillary Le Fort I osteotomy in segments (arch expansion, horizontal advancement, vertical lengthening, and clockwise rotation); sagittal split ramus osteotomies (minimal set-back); osseous genioplasty (vertical reduction); and septoplasty and inferior turbinate reduction. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

• **Figure 22-9** A 20-year-old man with left side hemimandibular elongation is shown. During his teenage years, he underwent attempted growth modification and orthodontic camouflage that included the removal of three bicuspids, without success. He had a lifelong history of obstructed nasal breathing. He was referred to this surgeon for evaluation and agreed to a comprehensive redo orthodontic and orthognathic approach. With the relief of dental compensation, his surgery included maxillary Le Fort I osteotomy in segments (minimal advancement, vertical adjustment, cant correction, arch expansion, and the correction of the curve of Spee); bilateral sagittal split ramus osteotomies (mandibular straightening and asymmetric correction); osseous genioplasty (asymmetry improvement); and septoplasty and inferior turbinate reduction. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 22-10** A teenaged boy with right side hemimandibular elongation. When he was between 10 and 14 years old, he was treated with growth modification attempts and then orthodontic camouflage. His overjet improved at the expense of the dental compensation, and the facial deformity remained. He was referred to this surgeon, who recommended stopping active treatment until the patient was skeletally mature. When he was 17 years old, he underwent redo orthodontics and an orthognathic approach. The orthodontics were carried out without extractions, which left the maxillary incisors procumbent. Clockwise rotation of the maxillomandibular complex as part of the orthognathic correction was helpful to overcome the facial disharmony. The patient's surgical procedures included maxillary Le Fort I osteotomy in segments (cant correction, horizontal advancement, clockwise rotation, arch expansion, and vertical lengthening); bilateral sagittal split ramus osteotomies (mandibular straightening and clockwise rotation); and septoplasty and inferior turbinate reduction. **A,** Facial and occlusal views when the patient was 14 years old, after failed growth modification and orthodontic camouflage.

Raijmakers and colleagues carried out a meta-analysis to determine gender differences when it came to the diagnosis of asymmetric mandibular excess.[101] Ten studies were reviewed, and these included a total of 275 affected patients. The meta-analysis showed a clear predominance of female patients in the study populations. The male and female patients had an equal distribution of left- and right-sided condylar overgrowth. The authors postulate that hormonal variations—especially of estrogen in women—may explain these differences. An alternative explanation put forth for this apparent female predilection is a difference in motivation between the sexes to seek the correction of their facial asymmetry (see Fig. 22-6).

Slootweg and Muller described four histologically different types of mandibular condylar hyperplasia.[116] They proposed a classification system that is based on histologic criteria, and they divided hyperplastic condyles into four types, depending on the arrangement and morphology of the various layers of the condyle. These condylar layers were the fibrous articular layer; the undifferentiated mesenchyme proliferative layer; the transitional layer; and the hypertrophic cartilage layer.

Villanueva-Alcojol and colleagues attempted to correlate demographic and clinical presentations of condylar hyperplasia with the described histopathologic features and then with the associated scintigraphic and clinical findings after treatment with high condylectomy during the active phase.[122] Interestingly, the authors were unable to find a correlation between the histologic type (as described by Slootweg and Muller[116]) and the uptake of the affected condyle on bone single photon emission computed tomography or between the patient's age and his or her histologic type.

The preferred treatment to correct the dysmorphology for all forms of condylar hyperplasia is surgical including the repositioning and recontouring of the bones in combination with orthodontics to align the teeth.* The extent of

*References 8, 17, 26, 31, 33, 37, 39, 52-54, 56, 59, 61, 96, 99, 102, 103, 111, 115, 118, 119, 121, 126

treatment depends on the presenting dysmorphology and the status of condylar growth. If ongoing condylar growth is documented, then a form of high condylectomy should be considered to arrest progressive dysmorphology.[20,21,40,42] High condylectomy (i.e., the removal of 4 mm to 5 mm of the condyle) and condylar shaving procedures (i.e., the removal of only 2 mm to 3 mm of the condyle) are options that are discussed in the literature. The documentation of cartilage islands that extend into the cancellous bone suggests that the pathology is not limited to the apparent cartilage surface. For this reason, some clinicians prefer the high condylectomy procedure, because it will also remove subcondylar bone; in theory, it will also more fully eliminate the potential of the growth center.

Hemimandibular Hyperplasia: Type I Condylar Hyperactivity

Type I hemimandibular hyperplasia is a dentofacial deformity that results in excessive growth in volume of the whole hemimandible. With this condition, there is three-dimensional enlargement of one side of the mandible, and this includes all aspects: the condyle, the condylar neck, the ramus, the body, and the symphysis. The anomaly terminates exactly at the symphysis of the mandible. In its pure form, this condition does not result in a significant shifting of the midline of the chin or of the mandibular dental midline to the contralateral side. The occlusion is rotated, but there is minimal to no crossbite. There is an increase in vertical height, but it does not involve widening of the affected side of the face. This three-dimensional enlargement of the mandible results in a notable asymmetric rotation of the face. There is visually apparent ipsilateral downward and medial projection of the ramus as well as of the angle and body of the mandible.

When the anomalous process begins before puberty, there will be more severe and characteristic secondary deformities of the maxilla, the contralateral mandible, and the positioning of the teeth. The secondary maxillary deformities follow the downward and medial growth of the ipsilateral mandible, and the occlusal plane becomes canted. The ipsilateral increase in vertical height on the affected side leads to an apparent decrease in facial height on the "normal" (contralateral) side. To the uninitiated, the facial appearance may be confused with Hemifacial Microsomia.

The natural history of this pure form of hemimandibular hyperplasia (Type I) is to progress and result in three-dimensional disproportion and asymmetry on both sides of the maxilla, the mandible, and the chin region. Fortunately, this form of asymmetric mandibular excess is rare as compared with hemimandibular elongation (Type II), which results in a less severe three-dimensional clinical deformity.

When hemimandibular hyperplasia is recognized in its active and progressive state, Obwegeser recommends a condylar shave to arrest the disease process and to prevent further progression.[23-25,68-91] Another reason why some clinicians prefer the partial condylectomy procedure is that it can be used as a method to shorten the posterior facial height. When the phenotype is characterized by primary vertical overgrowth with minimal to no horizontal deviation of the mandible, it can simultaneously be an effective way to restore the morphology. If the deformity remains active and is allowed to reach its endpoint, then the restoration of ideal facial aesthetics is problematic. The objectives of the *condylar shave procedure* are to arrest any further abnormal growth on the affected side; to prevent continued secondary deformities of the maxilla, the nose, and the contralateral side of the mandible; and to arrest any additional malpositioning of the teeth. The problem with this approach is that secondary procedures to correct the facial skeleton are still required in most cases. It remains unclear just how much of a deformity will be aborted by an open-joint procedure.

Practically speaking, however, a condylar procedure (e.g., condylar shave, high condylectomy) is not generally required, because growth has usually ceased by the time of diagnosis and surgical referral. This can be surmised by a review of the patient's previous records (e.g., radiographs, facial and occlusal photographs, dental models), or it can be confirmed by a bone scan. Definitive treatment of the dentofacial deformity through orthognathic and recontouring surgery is the usual approach once growth maturity and condylar arrest have occurred.

Functional Aspects

- Articulation errors in speech may result if a significant malocclusion is present (see Chapter 8).
- Predictable chewing and swallowing difficulties will result if a significant posterior open-bite malocclusion is present (see Chapter 8).
- The ability to comfortably close the lips together and their position at rest may be negatively affected depending on the extent of jaw malposition and dental malocclusion.
- Depending on the extent of deformity, the individual with asymmetric mandibular excess is likely to experience self-esteem and body-image issues (see Chapter 7).
- Nasal airway obstruction as a result of a deviated septum and turbinate enlargement with increased nasal airway resistance may be present and should be ruled out (see Chapter 10).
- Detrimental long-term effects on the dentition and the periodontium caused by traumatic malocclusion, the displacement of teeth outside of the alveolar housing, or previous camouflage orthodontic treatment may occur (see Chapter 6).
- A higher-than-average incidence of TMD has been reported in this form of dentofacial deformity (see Chapter 9).

Clinical Characteristics

- This deformity should not be confused with hemifacial microsomia, because the soft-tissue envelope (including

the external ear) is not hypoplastic on the affected side of the face.
- There is increased vertical height of the affected (ipsilateral) side of the face.
- The medial and downward shift of the ipsilateral mandible is most notable at the angle.
- There is a relative lateral and upward position of the contralateral mandible.
- The overall face has a "rotated" appearance.
- Mouth opening is without restriction.
- The ipsilateral corner of mouth is inferior but not posteriorly positioned.
- The cheek appears flat on the ipsilateral side.
- The width of the face on the ipsilateral side appears to be decreased.
- The maxilla is generally canted down on the ipsilateral side.

Dental Findings

- The crowns of the teeth on the contralateral side of the mandible tilt toward the ipsilateral side. They do so as a dental compensation to maintain occlusion with the opposing maxillary teeth, thereby avoiding crossbite.
- Lingual tilting of the mandibular alveolar ridge on the contralateral side is a secondary deformation as the (contralateral) lower jaw shifts lateral and assumes a superior position.
- The dental arches appear "twisted" by the slow process of three-dimensional growth distortion of the ipsilateral mandibular and the secondary deformations that occur in the contralateral side of the mandible and whole maxilla.
- If the ipsilateral excess mandibular growth is rapid, then the maxilla cannot respond at the same rate; this results in an ipsilateral posterior open bite.
- If the rate of ipsilateral excess mandibular growth is relatively slow, then maxillary dental hypereruption with secondary canting and the maintenance of occlusion are more likely.
- In most cases, the maxillary and mandibular dental midlines will closely match.

Radiographic Findings

- There is three-dimensional enlargement of the ipsilateral mandible, which terminates at the symphysis. The enlarged (ipsilateral) condyle also becomes "classically" deformed.
- The overall height of the body of the mandible is greater on the ipsilateral side.
- The inferior border and angle of the mandible are rounded on the ipsilateral side.
- Increased alveolar height between the inferior border and the root apices on the ipsilateral side is expected.
- The mandibular canal will be displaced downward on the ipsilateral side, often in close proximity to the inferior border.

Hemimandibular Elongation: Type II Condylar Hyperactivity

The dentofacial deformity called Type II *hemimandibular elongation* results in excessive growth on one side of the mandible without an overall three-dimensional increase in the volume of the whole affected side as seen with a Type I condition (i.e., hemimandibular hyperplasia; see Figs. 22-6 through 22-15). At the same time, hemimandibular elongation is not limited to just one aspect of the mandible. It results in a relative elongation (i.e. lateral shift) of all components of the ipsilateral lower jaw, including the condyle, the condylar neck, the ascending ramus, and the body. The condylar neck will be elongated and narrow, but the condylar head (i.e., the articulation of the temporomandibular joint [TMJ]) appears to be relatively normal in size and shape.

Obwegeser recognizes two distinct variations within the Type II hemimandibular elongation form of condylar hyperactivity.[23,24,25,68-91] In the first subgroup (i.e., the *"slender type"*), there is an elongated hemimandible on the affected side as well as a morphologic "stretching" of the angle of the mandible. The distinguishing morphologic feature is an obtuse gonial angle as compared with the contralateral side. The second subgroup (i.e., the *"non-slender type"*) has an angle of the mandible that looks very much like the "normal" contralateral side and yet the whole (ipsilateral) mandible is clearly elongated.

The clinical features that are always present with Type II hemimandibular elongation—and therefore useful findings that differentiate it from Type I hemimandibular hyperplasia—include a visual lateral shift of the chin midline and the mandibular dental midline to the contralateral side; a posterior crossbite on the contralateral side; and no significant increase in the posterior facial height from side to side. The most striking features of Type II hemimandibular elongation include the deviation of the chin and the mandibular dental midline to the opposite side with a posterior crossbite on the contralateral side and a class III molar relationship on the ipsilateral side. As stated, there will be no significant difference in the posterior facial height between the two sides of the face, but canting that has been recognized in the maxilla and mandible is likely to be present and will benefit from surgical correction.

To review, *hemimandibular elongation* is the preferred term for what has classically been referred to as "asymmetric mandibular excess." Interestingly, the deformity has usually progressed and done its damage by the time of clinical presentation to the surgeon. For this reason, a condylar shave is rarely warranted. In general, these deformities can be reliably managed with standard orthognathic techniques carried out at skeletal maturity in conjunction with effective

orthodontics to improve head and neck function and to enhance facial aesthetics (Fig. 22-6 through Fig. 22-14).

Functional Aspects

- Articulation errors in speech may result if a significant malocclusion is present (see Chapter 8).
- Chewing and swallowing difficulties resulting from the presenting malocclusion are typical (see Chapter 8).
- The ability to comfortably close the lips together and their position at rest will be negatively affected by the extent of jaw malposition and dental malocclusion.
- The individual with this jaw growth pattern is likely to experience self-esteem and body image issues directly related to the presenting facial asymmetry (see Chapter 7).
- Nasal airway obstruction as a result of a deviated septum and enlarged inferior turbinates with increased nasal airway resistance is likely present and should be ruled out (see Chapter 10).
- Detrimental long-term effects on the dentition and periodontium as a result of traumatic malocclusion, the displacement of the teeth outside of the alveolar housing, or previous camouflage orthodontic treatment may occur (see chapter 5 & 6).
- A higher-than-average incidence of temporomandibular disorder (TMD) has been reported with this anomalous pattern of dentofacial growth. Joint noise and

discomfort on the ipsilateral side are not infrequent (see Chapter 9).

Clinical Characteristics

- The pogonion of the mandible and soft-tissue chin prominence are shifted to the contralateral side.
- The lower lip is in front of (i.e., anterior to) the upper lip; this is the reverse of normal.
- Vertical mouth opening is usually undisturbed.
- The ipsilateral corner of the mouth is usually lower and more anterior than the contralateral side (i.e., canting is present).
- The profile line may be harmonious, but it more likely gives the impression of mandibular prognathism.
- The soft-tissue cheek region appears fuller on the contralateral side.
- The prominence of the cheekbone appears to be deficient on the ipsilateral side.
- There is no apparent vertical height difference between the two sides of the face.

Dental Findings

- The ipsilateral molars are in Class III malocclusion.
- The contralateral molars may be in Class I or Class II malocclusion.
- A posterior crossbite on the contralateral side is typical.
- The mandibular dental midline is shifted to the contralateral side.
- Tilting of the lower anterior teeth with the incisal surfaces toward the ipsilateral side is typical.
- Retroinclination of the lower incisors is generally seen.
- Lingual inclination of the contralateral mandibular posterior teeth is typical.
- The maxilla is often canted downward and forward on the ipsilateral side.

Radiographic Findings

- Ascending ramus asymmetry from side to side is frequent.
- A thick cortical plate along the inferior border of the mandible on the ipsilateral side is frequent.
- The ipsilateral mandibular canal may appear to be lower positioned (i.e., closer to the inferior border), better defined (i.e., encased in cortical bone), and in close proximity to the roots of the teeth as compared with the contralateral side.
- The overall visual appearance and the measurable length of the mandible indicate elongation on the ipsilateral side.
- The ipsilateral angle of the mandible may be more obtuse (i.e., slender) as compared with the normal (contralateral) side.
- The ipsilateral condylar neck will be long, but the diameter is typically not increased.
- When viewed on a posteroanterior cephalometric radiograph, canting of the maxillary occlusal plane may be seen (i.e., downward and forward on the ipsilateral side).
- When viewed on a posteroanterior cephalometric radiograph, canting of mandibular plane is typically seen (i.e., downward and forward on the ipsilateral side).

Assessing Jaw Growth Maturity

Skeletal scintigraphy with a technetium bone scan is a useful method for the assessment of difficult growth-related diagnostic problems of the mandibular condyle.[3,29,34,35,57,63,92,95,104] For patients with asymmetric mandibular excess, the state of residual growth may be clarified by the unequal ratio of uptake of technetium in each condylar head. Alternatively, an equal ratio of uptake shows that asymmetric growth has likely ceased. In difficult diagnostic cases, normal versus abnormal condylar growth can be further assessed by comparing the ratio of the uptake with the tabulated normative standards developed by Kaban and colleagues.[18,19,43-46] The cessation of mandibular growth can be more or less predicted when the uptake ratios approach 0.70, which is the adult norm. Skeletal scintigraphy (i.e., bone scan) may be useful during the making of decisions that involve the timing and extent of treatment when residual condylar growth remains uncertain. After the cessation of growth, there will be no advantage to an open-joint procedure. In this case, the correction of the dentofacial deformity with the use of standard orthognathic techniques is indicated.[5,107-109]

High Partial Condylectomy Procedure for Active Condylar Hyperactivity

The successful treatment of asymmetric mandibular excess requires the cessation of growth before definitive surgical correction. Knowledge of whether the condition is still active is assessed at the condylar site.[5,107-109] For the patient with *hemimandibular elongation,* the deformity has usually progressed and done its damage by the time of clinical presentation to the surgeon. In general, the presenting jaw deformities are best managed with standard orthognathic techniques that are carried out at skeletal maturity to improve both head and neck function and to enhance facial aesthetics. Alternatively, the *hemimandibular hyperplasia* deformity may be more gradual in its progression. In this case, if the condition is allowed to reach its endpoint, it may not be possible to achieve an ideal symmetric facial aesthetic result. A condylar shave procedure may be beneficial for the subgroup of patients with Type I hemimandibular hyperplasia to arrest ongoing abnormal growth on the affected

side; to prevent further secondary deformities of the maxilla, the nose, and the contralateral side of the mandible; and to arrest the malpositioning of the teeth.[20,21,40,42]

Some surgeons are relatively quick to suggest a high condylectomy or a condylar shave, because they feel that little harm will be done and that such a procedure has the potential to limit the extent of orthognathic surgery that will be required. Most surgeons remain hesitant when it comes to performing a direct condylar procedure, because they recognize the law of unintended consequences and the potential for the deterioration of TMJ function. In general, I agree with this conservative approach when considering an open condylar procedure.

Lippold and colleagues as well as other researchers have suggested that minimal harm occurs from a "high condylar shave."[51] Until recently, critical reviews of an invasive TMJ approach have not been forthcoming. Saridin and colleagues completed an evaluation of temporomandibular function after high partial condylectomy in a consecutive series of individuals with unilateral condylar hyperplasia (N = 33).[110] The study group included individuals with unilateral condylar hyperplasia whose conditions were considered to be active; in other words, the mandibular asymmetry appeared to be clinically progressive, and the bone scan was positive. The subjects then underwent high condylectomies (N = 33). The patients were compared with a control group that was matched for age and gender (N = 31). All patients and all members of the control group filled out a history questionnaire and underwent a clinical examination in accordance with the research diagnostic criteria for temporomandibular disorders. The patients were studied for an average of 4.3 years after the condylectomy was carried out (range, 0.6 to 13.3 years). The results of the study indicate that patients with unilateral condylar hyperplasia who undergo condylectomy in an attempt to arrest progressive mandibular asymmetry will have more joint-related temporomandibular problems and a higher persistence of long-term pain as compared with age- and gender-matched controls.

Presurgical Orthodontic Treatment

Among patients who are affected by these mandibular excess growth patterns, orthodontic maneuvers that were carried out earlier during their lives to modify growth or as camouflage approaches to neutralize the occlusion should be overcome with further orthodontic mechanics before orthognathic surgery. Frequently seen scenarios include the following: (1) orthodontic overexpansion of the maxillary arch to correct crossbites; (2) hypereruption of the molars on one side and intrusion on the other side to correct canting; (3) lingual tipping of the mandibular molar or premolar crowns on the contralateral side and buccal tipping of the molar or premolar crowns on the ipsilateral side; and (4) retroclining of the lower anterior teeth to correct the overbite. All of these orthodontic techniques may have been tried with the hope of neutralizing the occlusion and avoiding surgery. These camouflage orthodontic mechanics hamper the preferred surgical positioning of the jaws to achieve maximum facial harmony, and they will also leave the occlusion prone to late relapse and the dentition susceptible to long-term periodontal breakdown (see Chapter 5).

In preparation for an orthognathic correction, the orthodontic treatment of each jaw should achieve the correct positioning of the teeth within the respective alveolar process (see Chapter 5). If this is accomplished, the clinicians can best achieve maximum mirror-image skeletal symmetry, Euclidian facial proportions, and a long-term stable occlusion with periodontal health (see Chapter 6).

Surgical Approach

The Influence of Chin Asymmetry on Perceived Facial Attractiveness

Naini and colleagues undertook an investigation with the objective of assessing how severe an asymmetry at the chin point would have to be to influence perceived attractiveness.[64] Idealized two-dimensional frontal facial views were created with the use of computer software in which the chin point was altered from side to side in 5-mm increments from 0 mm to 25 mm. These images were then rated on a seven-point Likert scale by a preselected group of observers that included orthognathic patients before treatment, clinicians, and laypeople (n = 185 observers). The study confirmed that, in the frontal view, chin asymmetries of 10 mm or greater are perceived as being significant, whereas those of 5 mm or less largely go unnoticed. The greater the degree of asymmetry (i.e., >10 mm), the more noticed it will be by an observer and the greater the patient's desire for correction. Both clinician and patient ratings were similar and found to be more critical than the ratings given by laypeople. The images that were considered the most attractive showed perfect bilateral symmetry of the chin region. The lowest-rated images showed the highest degrees of asymmetry of the chin. Combined vertical and horizontal asymmetries were rated slightly worse than horizontal asymmetry alone.

Hemimandibular Hyperplasia (Type I)

If the *hemimandibular hyperplasia deformity* remains active and is allowed to progress to its endpoint, it may not be possible to achieve an ideal symmetric facial aesthetic result. For this reason, a high condylar shave to arrest further abnormal growth on the affected side and to prevent ongoing secondary deformities (i.e., of the maxilla, nose, and contralateral side of the mandible; malpositioning of the teeth) should be considered if condylar hyperactivity remains, as described previously.[20,21,40,42]

Details of the definitive maxillofacial reconstruction will depend on the patient-specific morphologic findings (see

Figs. 22-2 through 22-5).[30,32,97,98,105] A wide spectrum of three-dimensional maxillofacial distortions caused by the primary anomaly and the secondary deformities is expected. In addition to standard techniques (i.e., Le Fort I osteotomy in segments, sagittal split ramus osteotomies of the mandible, osteotomy of the chin), mandibular inferior border recontouring will often be beneficial (see Chapter 12). The recontouring includes inferior border resection and rotary drill bur modification from the angle of the mandible to the chin on the ipsilateral side, as indicated. Inferior border augmentation on the contralateral side is not usually recommended because, over time, visible irregularities on the grafted side can easily occur after partial graft resorption. Segmentation of the maxilla (i.e., into two or three pieces) is also generally required to correct the cant and the arch form.

Hemimandibular Elongation (Type II)

The *deformities of hemimandibular elongation* are best managed with standard orthognathic techniques carried out at skeletal maturity to improve both head and neck function and to enhance facial aesthetics (see Figs. 22-6 through 22-14). This will include, at a minimum, sagittal split ramus osteotomies of the mandible. If the maxilla is secondarily deformed (i.e., canted, with a shift of the dental midline and an altered arch form), a Le Fort I osteotomy with three-dimensional repositioning is also required. An oblique osteotomy of the chin will likely further improve facial symmetry and proportions (see Chapter 12). The need for a high condylar shave to arrest growth remains limited, and this procedure is only considered in the presence of documented progressive active disease at the time of diagnosis.

Complications, Informed Consent, and Patient Education

Orthodontists and surgeons are frequently asked to evaluate jaw disharmonies and malpositioned teeth and then to attempt to alter nature's events. With an understanding of the natural progression of the uncorrected asymmetric mandibular excess growth anomaly and with knowledge of how specific interventions will affect head and neck function and facial aesthetics, predictable results are generally achieved. Complications and patient dissatisfaction will always occur in a small percentage of individuals. In the setting of asymmetric mandibular excess, obtaining the desired occlusion is more or less predictable. The expected outcome is an improvement in the facial asymmetry with persistent minor discrepancies. The clinician's ability to communicate the potential risks, complications, alternative approaches, and expected results of the recommended treatment to the patient and the patient's family is essential to the achievement of a favorable outcome. When the patient, the family, and all treating clinicians are fully informed, shared responsibility for the treatment result is more likely (see Chapter 16).

Malocclusion after Orthodontics and Orthognathic Surgery

There are inherent biologic challenges to the orthodontic movement of the teeth within the alveolar process and to the surgical repositioning of the jaws or jaw segments in the individual with an asymmetric mandibular excess growth anomaly. This includes the technical aspects of the repositioning, the initial healing requirements, and the difficulties associated with the long-term maintenance of the mechanically relocated teeth, jaws, and jaw segments. When following sound biomechanical and aesthetic principles, clinicians carry out orthodontic treatments and surgical procedures; in most cases, the results are effectively maintained. Potential intraoperative technical difficulties associated with sagittal split ramus osteotomies of the mandible and maxillary Le Fort I osteotomy can result in immediate early malocclusion, but these problems are generally preventable (see Chapter 17). In the teenager, timing surgery to limit concern about ongoing mandibular growth afterward is more problematic with asymmetric mandibular excess than with most other patterns of dentofacial deformity; this is discussed in more detail earlier in this chapter. All of these factors must be taken into account to achieve and then maintain the desired results.

Temporomandibular Disorders: The Effects of Orthodontics and Orthognathic Surgery

It is estimated that an average of 32% of the population report at least one symptom of TMD, whereas an average of 55% demonstrate at least one clinical sign. TMD includes various symptoms and signs of the TMJs, the masticatory muscles, and the related structures. The symptoms and signs may include a spectrum of referred head and neck pain; joint noise (e.g., popping, clicking, crepitus); reduced or altered mandibular movements caused by muscle spasm or disc displacement with or without reduction; condylar head erosion; and pain on direct palpation of either of the TMJs or the masticatory muscles. Occlusal factors (i.e., degrees of malocclusion) are often claimed to be associated with TMD. Asymmetric mandibular excess is associated with TMD more frequently than many other dentofacial deformities. The correction of the presenting jaw deformity and malocclusion through effective orthodontics and orthognathic surgery may relieve symptoms and signs of TMD in some patients, but this is not predictable for each individual patient. As stated earlier in this chapter, Saridin and colleagues found that the completion of a partial condylectomy on the ipsilateral side was associated with a higher incidence of TMD (see Chapter 9).[110] This should give the

clinician pause before he or she agrees to perform a condylectomy procedure.

Conclusions

Obwegeser believes that *asymmetric mandibular excess growth anomalies* are caused by two different growth regulators that are located entirely within the cartilaginous bony surface of the condylar head. This results in two different basic patterns of clinical presentation. The first, *hemimandibular hyperplasia,* is a more rare form that is characterized by an increase in the volume of all parts of the affected side of the mandible, with secondary deformities of all adjacent skeletal structures. If hemimandibular hyperplasia remains active and is allowed to reach its end deformity, the achievement of ideal facial symmetry is less likely. For this reason, if this condition is diagnosed during its active phase, a high condylar shave maybe advisable to prevent its progression. The second form of presentation, *hemimandibular elongation,* is more common; it is characterized by the elongation of one side of the mandible, and it results in the displacement of the midline of the chin and the dentition to the contralateral side. In most cases, hemimandibular elongation is best managed with standard orthognathic techniques carried out at skeletal maturity to improve both head and neck function and to enhance facial aesthetics.

- Conclusions

A frequently seen pattern of facial disharmony has the common denominator of a significant degree of vertical and horizontal (sagittal) deficiency in the maxilla and mandible. Measuring the ratio of the lower facial height (i.e., the subnasion to the menton) to the upper facial height (i.e., the glabella to the subnasion) will confirm that the lower height is diminished. The height of the alveolar process in both jaws is reduced.[23] The visual presentation of the face includes an apparent redundancy of the soft-tissue envelope of the lower face, thereby creating "chubby cheeks" in the adolescent and a prematurely aged look by early adulthood.

Clinical examination of the individual with a short face growth pattern will generally confirm a pseudoprominence of the nose; an acute nasolabial angle; a measurable and visually perceived short lower facial height with a disproportionate facial width-to-height ratio; and either a prominent pogonion (more frequent with a Class I deep bite) or a weak chin (more common with a Class II excess overjet).[3,10,11,20,21,35,39,40] Normally, there is a 1 : 2 relationship between the distance from the base of the nose to the upper lip and the distance from the lower lip to the chin. In the individual with a short face growth pattern, the relationship is closer to 1 : 1.[15,42,43,56] The labiomental sulcus is deep and the lower lip is everted, thereby further confirming the degree of mandibular deficiency. The maxillary incisors are often completely covered by the upper lip, which creates an edentulous appearance in repose and an unfavorable "no gingiva" smile. With the teeth in occlusion, the oral aperture appears closed and the upper lip projects forward, often in front of procumbent incisors. Individuals are frequently described as having a sad or unhappy look in repose as a result of the downturned oral commissures and the closed aperture. The reduced lower facial height causes the everted and prominent lips that would otherwise have appropriate shape and volume if the facial height and horizontal projection of the jaws were restored. In the profile view, the nose appears long and prominent. There is often a lateral flaring of the nostrils with a "hanging columella."

Classically, there is a deep bite with either marked anterior crowding or excessive flaring with less dental crowding.[34] There may be a Class II malocclusion with greater than average overjet.[50,51] If so, the mandible has greater deficiency than the maxilla, and the pogonion will lack prominence. Individuals with Class I deep bite without excess overjet are more likely to have a retropositioned A-point as compared with the B-point (i.e., a counterclockwise rotated maxillomandibular complex) and a prominent pogonion. The maxillary and mandibular planes are often nearly horizontal, which results in a "square jaw" facial appearance.

Functional Aspects

- Articulation errors in speech and altered swallowing mechanisms that result from the small jaws, the Class II

deep-bite malocclusion, and the limited intraoral volume for the tongue are expected (see Chapter 8).
- Difficulties with chewing and with lateral and protrusive mandibular movements as a result of the Class II deep-bite malocclusion are expected (see Chapter 8).
- A spectrum of upper airway sites of obstruction often exists with the short face growth pattern. This includes obstructions at the intranasal, palatopharyngeal (retropalatal), and glossopharyngeal (retroglossal) locations. The incidence of obstructive sleep apnea is increased in this patient population and should be ruled out (see Chapter 10 & 26).
- Detrimental long-term effects on the dentition and the periodontium as a result of any traumatic malocclusion, the crowding of the teeth in the limited alveolar housing, and previous camouflage orthodontic treatment may be seen (see Chapter 5 & 6).
- A higher incidence of temporomandibular disorders in the form of masticatory muscle discomfort as a result of the short facial height and the deep-bite malocclusion has been reported (see Chapter 9).

Clinical Characteristics

- Absence of maxillary tooth show beneath a relaxed upper lip
- Limited tooth and no gingiva show with broad smile
- Acute nasolabial angle
- Depressed pyriform rims
- An apparent fullness of the cheeks and a squareness of the overall face
- An apparent prominent and elongated nose when viewed in profile
- Procumbent everted lips, turned down corners of the mouth, and a closed aperture
- An excessively deepened and elongated labiomental fold
- Soft-tissue bunching that eventually results in perioral creases (i.e., marionette lines)
- Early and deep jowl formation by middle age
- Premature loss of any semblance of an attractive neck–jaw angle

Dental Findings

- Class II excess overjet malocclusion is common, but a Class I deep bite is also frequent.
- A deep impinging bite with palatal irritation is a frequent finding.
- Dental crowding with flaring of the incisors in each arch is also a frequent finding.

Radiographic Findings

- The total anterior facial height is decreased (i.e., from the nasion to the menton).
- The lower anterior facial height is short (i.e., from the subnasion to the menton).
- Horizontal retrusion is measurable at the A-point and the B-point in both jaws.
- Disproportion in the ratio of the facial width to the facial height is measurable on an anteroposterior cephalometric radiograph or a computed tomography scan.
- Excessive procumbency of the maxillary and mandibular incisors is frequently measurable.
- Excessive flattening (i.e., counterclockwise rotation) of the maxillary and mandibular planes is frequently measurable.
- Decreased alveolar bone height associated with the maxillary incisors is measurable (i.e., the distance from the floor of the nose to the incisal edge).
- Decreased alveolar bone height associated with the mandibular incisors is measurable (i.e., the distance from the short menton to the incisal edge).

Treatment Indications and Objectives

The indications for treatment in a patient with a short face growth pattern may be to improve function (e.g., occlusion, chewing, swallowing, speech, breathing, lip posture), but another compelling aspect is typically the enhancement of facial aesthetics. The visually aesthetic advantages of the surgical lengthening and projection of the short and retrusive lower face toward Euclidian proportions are immediately apparent and do not require quantification.[32,33,58]

To restore facial proportions and preferred facial aesthetics, there must be both vertical and horizontal expansion of the maxillomandibular complex.[54] Accomplishing these objectives will eliminate cheek and lip region bunching and distortion and restore a pleasing soft-tissue envelope. When this is done, a youthful oral aperture is restored. The corners of the mouth are no longer downturned, and the lips will be separated when they are at rest. The upper vermillion increases in volume, and the labiomental fold flattens. The maxillary incisors can be seen in repose, and the gingiva is visible with smile. The nose no longer appears excessively prominent, and the nasolabial angle improves. The jowls diminish, and the length-to-width ratio of the face is restored. The shape of the face changes from square to oval with the restoration of the natural contours and attractive ogee curves. The overall facial aesthetic changes from sad and older appearing to younger looking and more attractive (Figs. 23-1 through 23-7).

The Role of Growth Modification in the Preadolescent Patient

Individuals with lower anterior facial height deficiency can frequently be identified at an early age. They tend to have an acute (flat) mandibular plane angle with a deep bite.[25] This is accompanied by an upward (counterclockwise) rotated anterior mandible that results in a prominent-appearing pogonion.

• **Figure 23-7** A 26-year-old woman with a short face growth pattern arrived to discuss her maxillofacial issues. During her early teenage years, she underwent a full course of orthodontics. Her maxillary lateral incisors were congenitally absent, and the spaces were orthodontically closed, partially by tipping the canines forward. The maxillary incisor root resorption was significant. There was crowding in the mandibular arch with a degree of procumbency. The patient had an interest in improving her weak profile and her edentulous look. The patient's history confirmed heavy snoring, restless sleeping, and daytime fatigue. Examination confirmed a deviated septum and hypertrophic inferior turbinates. Maxillary retrusion resulted in the close proximity of the soft palate to the pharyngeal wall. A retrusive mandible resulted in the close proximity of the tongue to the posterior pharyngeal wall. An attended polysomnogram confirmed mild obstructive sleep apnea. Evaluation by a periodontist and an orthodontist confirmed the advantage of a comprehensive approach to improve the airway, to achieve a more balanced facial appearance, and to improve long-term periodontal health. A trial of continuous positive airway pressure improved daytime alertness, but the patient's feelings of claustrophobia prevented its use. Periodontal evaluation with gingival grafting and maintenance was carried out. Orthodontic appliances were placed with limited dental repositioning of the maxillary incisors as a result of baseline root resorption. The patient's surgery included maxillary Le Fort I osteotomy in segments (horizontal advancement, vertical lengthening, arch form correction, and clockwise rotation) with interpositional graft; bilateral sagittal split ramus osteotomies (horizontal advancement); and osseous genioplasty (vertical lengthening) and limited horizontal advancement) with interpositional bonegraft. As a result of treatment, the patient has had a relief of her snoring, more restful sleeping, and improved alertness during the day. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

Orthodontic growth modification treatment during preadolescence attempts to increase the eruption of the posterior teeth.[19,31,44] If this is successful, while lengthening the anterior facial height, this will cause the mandible to rotate clockwise, thereby resulting in a downward and backward shift at the pogonion. Unfortunately, this backward rotation of the mandible is not favorable to the profile unless it is also accompanied by horizontal advancement. For the preadolescent with a Class II excess overjet and a short face growth pattern, cervical headgear has been used to apply extrusion forces to the posterior maxillary dentition; however, this tends to simultaneously "set back" the already retrusive maxilla. As an alternative, functional intraoral appliances have also been tried in an attempt to erupt the posterior dentition. These orthopedic maneuvers, when followed by orthodontic mechanics, may achieve a neutralized occlusion in the child with maxillomandibular deficiency. However, this treatment cannot achieve the vertical height and the horizontal projection required to normalize the facial proportions and improve the airway.[4,7,22,52,59]

Since the late 1970s, Delaire and colleagues have attempted to achieve horizontal advancement and vertical lengthening of the maxilla with a face mask apparatus.[6] The best data indicate that use of the Delaire mask to increase maxillary projection is only effective for young children who are less than 8 to 10 years old, when the sutures remain open.[48,49] Unfortunately, with the short face growth pattern, Delaire face mask therapy is simultaneously counterproductive on the baseline deficient mandible, even if it effectively projects the maxilla.

Definitive Reconstruction

Timing of Orthognathic Surgery

The best evidence available indicates that, when orthognathic surgery is performed on a patient with a short face growth pattern (i.e., maxillomandibular deficiency) as early as the completion of the adolescent growth spurt, the result will be stable from a growth perspective. Further sagittal growth of either the maxilla or the mandible almost never occurs.[45] Vertical growth in both the mandible and the maxilla is also not likely to continue, but, if it does, it should be proportionate. Therefore, proceeding with orthognathic

surgery in the individual with maxillomandibular deficiency as early as the age of 13 or 14 years—but only after the eruption and orthodontic alignment of the teeth—is generally safe from a growth perspective.

Orthodontic Preparation for Orthognathic Surgery

Class II, Division I

The basic presurgical orthodontic goals for the individual with Class II, Division I malocclusion include the following: 1) aligning each dental arch independently; 2) placing the incisors in their preferred anteroposterior and vertical plane position; 3) anticipating a stable arch compatibility after surgery; and 4) considering segmental maxillary osteotomies to accomplish these goals.

Extractions from the maxillary arch are generally not indicated. There is often an excessive curve of Spee in the mandible, and the full leveling of the curve after surgery is generally preferred. This is rapidly accomplished via the extrusion of the premolars after surgery with the use of vertical elastics. The alternative to preoperative leveling involves incisor intrusion. Less clockwise rotation of the mandible at operation should be expected when incisor intrusion has been carried out to flatten the curve of Spee.

The establishment of eventual arch compatibility through orthodontics and surgery requires the following:

- Compatible intercanine widths either through orthodontics alone or with the help of maxillary segmental osteotomies
- Bonding or banding and leveling of the first and second molars
- Anticipating similar maxillary and mandibular arch forms either through orthodontics alone or with the help of maxillary segmental osteotomies

Postsurgical orthodontics will maintain the arch form and bring the teeth into final occlusion. The full leveling of the curve of Spee and closure of the extraction spaces in the mandible is usually accomplished during the detailing phase after surgery.

Class II, Division II

The basic presurgical orthodontic goals for the Class II, Division II malocclusion include the following: 1) the need for the proper vertical and anteroposterior positioning of the maxillary and mandibular incisors; 2) the need to level the curve of Spee; and 3) the need to anticipate coordinated dental arches after surgery, 4) which may include or require segmental maxillary osteotomies.

In general, the maxillary incisors will require labial tipping to correct the inclination. For severe deep-bite cases, it is advisable to fully level the curve of Spee in the mandibular arch after surgery. Preoperative glass ionomer bite planes cemented to the mandibular molars may be helpful, but unwanted molar intrusion can occur. Another option is to bond metal or ceramic "bite turbos" to the lingual surfaces of the maxillary incisors. This provides an anterior bite plane to open the bite without molar extrusion.

Anticipating the advantages of the surgical segmenting of the maxilla to level the curve of Spee and to correct arch-width discrepancies is often helpful. The postsurgical final leveling of the curve in the mandibular arch is generally both efficient and effective.

Basic Surgical Approach

By definition, for the patient with a moderate to severe short face growth pattern, there will be a need to simultaneously surgically reposition the maxilla, the mandible, and the chin region if the normalization of both the facial height and the facial projection is desired.[1,2,5,8,9,27-30,36-41,53,58] For the patient with a Class I short face growth pattern, simply lengthening the maxilla to improve the upper lip to tooth relationship through Le Fort I osteotomy with maintenance of the occlusion will cause an undesirable backward rotation of the mandible. This "single jaw" approach prevents the necessary horizontal advancement of the maxillomandibular complex. Unfortunately, the inability to achieve adequate sagittal (horizontal) projection of the maxillomandibular complex is likely to result in aesthetic disappointment. For this reason, bimaxillary surgery (i.e., Le Fort I and bilateral sagittal split ramus osteotomies) is required for the correction of a short face growth pattern. In borderline cases, a limited camouflage approach involving an osseous genioplasty with significant vertical lengthening and a degree of horizontal advancement may at least provide some aesthetic enhancement without introducing surgical deformity (see Chapters 37 and 40).

Orthognathic planning begins with the making of decisions about the magnitude of vertical lengthening, horizontal advancement, and clockwise rotation required in the maxilla. These decisions are primarily based on aesthetic judgments that are made when examining the patient in the natural head position (see Chapter 12). A common mistake is to err on the side of insufficient lengthening of the midface out of a belief that the short upper lip will not accommodate the skeletal lengthening. Experience has shown that the hypotonic (short) upper lip will stretch and gain function when the maxilla is surgically expanded (i.e., horizontal advancement and vertical lengthening). In addition, as the maxilla is surgically lengthened and simultaneously advanced and clockwise rotated, the pyriform rims and the anterior nasal spine are thrust forward and inferiorly, thus further stretching and filling out the soft tissues of the lower aspect of the nose and the upper lip. When the anterior floor of the nose (i.e., the alveolar bone height above the incisors) is short, consideration should also be given to graft augmentation of the anterior floor at the rim just above the incisors to further improve nasal base aesthetics. The need for this should be definitively reassessed during the operation, after the maxilla is stabilized with plate and screw fixation in its new location. In addition to maxillary

reconstruction, the mandible requires horizontal advancement and often clockwise rotation. This is accomplished through sagittal split ramus osteotomies. In most cases, an osseous genioplasty provides access to vertically lengthen the deficient anterior mandibular alveolar height and interpositional grafting is required. Horizontal advancement of the chin is not generally beneficial.

The previous line of thinking was that vertical lengthening, especially in combination with horizontal advancement of the maxilla, is unstable and inadvisable.[5,13,14,17,18,24,46,57] We now know that, with full mobilization of the down-fractured maxilla, lengthening and advancement can be carried out with occlusal stability and the routine achievement of improved facial aesthetics. This requires the following: 1) well-designed and executed osteotomies; 2) the full mobilization of the down-fractured maxilla; 3) rigid plate and screw fixation; 4) the placement of an interpositional graft (e.g., autogenous or allogenic corticocancellous iliac bloc graft) into the gaps between the zygomatic buttress and the pyriform rim on each side; 5) additional rigid plate and screw fixation to secure each graft; and 6) appropriate postoperative management to control bite forces during the early healing phase at the Le Fort I osteotomy sites (see Chapter 15). Kretschmer and colleagues studied the incidence of relapse after Le Fort I osteotomy with vertical lengthening with both single piece and segmental Le Fort I osteotomies (see Chapter 17).[16] The authors' data confirms that, when significant advancement and lengthening at the Le Fort I osteotomy site are carried out, key factors to achieve postoperative stability include the interpositional bone grafting of defects and rigid plate and screw fixation. Interestingly, the researchers did not find segmentation of the maxilla during bimaxillary procedures to be a significant cause of either skeletal or dental relapse.

Immediate Presurgical Planning

The immediate presurgical planning takes into account collaborative clinical efforts among the orthodontist, the surgeon, the patient, and the patient's family that will have been ongoing since the initial consultation visits. Depending on the condition of the dentition and its supporting structures, the restorative dentist and the periodontist may also have been intricately involved.

The patient's specific medical and dental records are reviewed, including radiographs (e.g., computed tomography scans; panoramic, lateral, and posteroanterior cephalometric radiographs; periapical images); photographs (facial and occlusal); and dental models. Immediate presurgical records (i.e., within 2 to 6 weeks of surgery) will most importantly include facial measurements obtained from direct visual examination; alginate impressions of the maxilla and mandible; an accurate centric relation bite registration; and face-bow registration. First, broad-stroke decisions are made regarding the preferred vector changes for each jaw; only then can the precise millimeter distances and angular changes required for each jaw to achieve the desired result be determined (see Chapter 12). Analytic model planning is carried out on the articulated dental casts with use of the Erickson Model Table. Splints are constructed to assist with the achievement of the precise occlusion and preferred facial aesthetics in the operating room (see Chapter 13).

Postsurgical Orthodontic Maintenance and Detailing

If the Class II excess overjet patient has a presurgical habit of posturing the mandible forward (i.e., a dual bite), there may also be a tendency to do so during the immediate postoperative healing phase, thereby producing a pseudo-anterior crossbite. Intermittent intermaxillary elastics are used during this time to retrain the masticatory muscles, to provide motion in the temporomandibular joints, to increase patient comfort, and to confirm the stability of the occlusion. If a splint is used, when it is removed (e.g., 5 weeks after surgery), the patient should immediately (ideally within 24 hours) return to the orthodontist for the placement of a continuous maxillary arch wire. In general, the maintenance of the new arch form after segmental surgery is the most challenging aspect of the postsurgical orthodontic phase of treatment.

The postsurgical orthodontic objectives should be to maintain the surgical result and to bring the teeth into ideal occlusion. In the patient in whom the curve of Spee is to be fully leveled postoperatively, the use of vertical elastics to close the mid arch open bites will also be a priority.

Complications, Informed Consent, and Patient Education

The orthodontist and the surgeon are asked to evaluate the individual with maxillomandibular deficiency and to then attempt to alter nature's events. By understanding the expected effects of the uncorrected short face growth pattern (i.e., airway, aesthetics, long-term dental health) and with knowledge of how specific orthodontic and orthognathic interventions will alter head and neck function and enhance facial aesthetics, a successful outcome is expected in most cases. An understanding of the potential risks in comparison with the anticipated benefits of each intervention is taken into account, because complications and dissatisfaction will always occur in a small percentage of individuals. The clinician's ability to communicate the potential risks, complications, alternative approaches, and benefits of the recommended treatment to the patient and their family is essential. The patient's informed decision to proceed provides the basis for shared responsibility of the expected convalescence and long-term outcome (see Chapter 16).

Malocclusion after Orthodontics and Orthognathic Surgery

There are inherent biologic challenges to the orthodontic movement of teeth within the alveolar process and the

surgical repositioning of the jaws or jaw segments after osteotomies in a patient with a short face growth pattern. This includes the technical aspects of the repositioning; the initial healing requirements; and the difficulties associated with the long-term maintenance of the relocated teeth, jaws, and jaw segments. When following sound biomechanical and aesthetic principles, clinicians carry out orthodontic treatment and surgical procedures that involve correction and then successful maintenance of the result in most cases. Potential intraoperative technical difficulties associated with sagittal split ramus osteotomies of the mandible and with maxillary Le Fort I osteotomy can result in immediate (early) malocclusion, but this is preventable in most cases. Ongoing growth after surgery is rarely an issue with a short face growth pattern. Although condylar resorption after orthognathic surgery is not entirely predictable, it is uncommon (see Chapter 36). The orthodontic removal of dental compensations and the placement of the teeth solidly in the alveolar housing will best ensure a long-term stable occlusion and periodontal health. All of these factors are taken into account to achieve and then maintain a favorable result (see Chapter 17).

Temporomandibular Disorders: The Effects of Orthodontics and Orthognathic Surgery

It is estimated that an average of 32% of the population reports at least one symptom of temporomandibular disorder, whereas an average of 55% demonstrate at least one clinical sign. Temporomandibular disorder includes various symptoms and signs of the temporomandibular joints, the masticatory muscles, and the related structures. The symptoms and signs may include a spectrum of referred head and neck pain; joint noise (e.g., popping, clicking, crepitus); reduced or altered mandibular movements (i.e., muscle spasm or disc displacement with or without reduction); condylar head erosion; and pain on direct palpation of either temporomandibular joint or of the masticatory muscles. Occlusal factors (i.e., degrees of malocclusion) are often claimed to be associated with temporomandibular disorders. Interestingly, patients with maxillomandibular deficiency (i.e., the short face growth pattern) tend to have higher maximum biting forces than those with normal or long vertical facial dimensions.[12,26,47,55] This has been documented to be statistically significant during swallowing, simulated chewing, and maximum biting.[31] Affected patients often claim to have difficulty chewing through foods and also experience masseter muscle discomfort. The individual with a short face growth pattern and a Class II significant overjet malocclusion is likely to have an uncomfortable dual bite, whereas the patient with a Class I deep bite is more likely to have temporomandibular joint clicking; in the latter case, there is no reason to believe that progressive temporomandibular joint pathology will occur (see Chapter 9).

Conclusions

The dentofacial disharmony referred to as *short face growth pattern* has the common denominator of a significant degree of vertical and horizontal deficiency in the maxilla and the mandible. The aesthetic presentation generally includes an apparent fullness of the cheeks and a deficiency of the lower face in the adolescent, with a prematurely aged look present by early adulthood. To achieve Euclidian facial proportions with enhanced facial aesthetics, there must be both vertical and horizontal expansion of the maxillomandibular complex. Accomplishing these objectives should successfully eliminate soft-tissue bunching, restore a more pleasing facial appearance, improve the upper airway, and correct any presenting malocclusion.

- Conclusions

Bimaxillary dental protrusion can occur in any racial group, but facial divergence (i.e., convexity) and lip prominence are strongly influenced by racial and ethnic characteristics.[37,67,95,107] Greater degrees of lip and incisor prominence tend to occur in Asians, Africans, and Latinos as compared with Caucasians.[68,75] In Caucasian populations, dental protrusion is more common among individuals of Mediterranean background than among those from more northern European regions. The Australian aborigines, who are classified as Caucasoid, have greater degrees of facial and dental protrusion. Etiologic factors that favor bimaxillary dental protrusion with anterior open bite include heredity; paraoral habits (e.g., thumb sucking); and the presence of strong protrusive tongue muscle forces in combination with weak bilabial (lip) forces.[103,104,120] The common physical findings include flaccid lips, procumbent maxillary and mandibular incisors, and an anterior open bite.

Drummond compared the facial morphology of Caucasian Americans to that of African Americans.[35] He found that Africans more frequently have a protrusive and strong tongue with loose, flaccid lips. These altered forces during growth are known to gradually push the anterior teeth into a procumbent position. The resulting proclination of the teeth in combination with the thickness of the lips make the lower face appear to be more full. Altemus compared the cephalofacial relationships of Caucasian, African, Chinese, Japanese, Navajo Indian, and Australian aboriginal individuals.[3] He concluded that the relative straightness of an individual's facial profile is very much a reflection of the underlying skeletal parts. He also found that, although the upper facial profiles (i.e., the forehead, orbits, and cheekbones) of the varied racial groups appeared to be remarkably similar, the lower facial profiles (i.e., the maxilla, mandible, and chin region) did not. The position of the anterior teeth and lips of African children were found to be more protrusive as compared with those of Caucasians. Sushner studied 100 lateral facial photographs of "attractive" Africans.[119] He used the Steiner, Holdaway, and Ricketts cephalometric standards to analyze the "attractive" African facial photographs,[53,88] and he concluded that the soft-tissue profiles of the individuals in those photographs were significantly more protrusive than the accepted Caucasian standards. He went on to establish African cephalometric norms. Similar studies completed by Guinn and Connor confirmed that the African soft-tissue profile is more protrusive and significantly different from Caucasian cephalometric norms.[5,24,25,50]

Peck and Peck set out to determine the public's concept of beauty as related to the Caucasian profile.[94] The authors found that the general public admires a more full face as compared with the accepted cephalometric normative data and clinical orthodontic standards of the day (e.g., four bicuspid extractions with orthodontic retraction). These

authors pointed out that the "ultimate source of our aesthetic values should be the people [i.e., public opinion], not just ourselves [i.e., clinicians]." Foster studied facial aesthetic preferences among various groups by using profile silhouettes.[44] The evaluators included Africans, Caucasians, and Chinese individuals; art students; general dentists; and orthodontists. The results confirmed a common aesthetic preference for the position of the lips in profile to be within 1 mm to 2 mm of each other. Another finding was that all groups consistently associated fuller lips with a more youthful appearance. Farrow and colleagues attempted to discover what African Americans find attractive about their own profiles.[40] The study results found that the preferred aesthetic profile involved slight convexity and more protrusion as compared with standard Caucasian cephalometric norms. A review of the literature confirms that, as a group, African Americans differ from Caucasian Americans with regard to dental, skeletal, and soft-tissue facial parameters.[2,31,43,58,122] For both groups, facial convexity is a preferred feature.[28,30,76,77,100] However, the question remains: at what point does attractive fullness (i.e., convexity) of the profile become dysmorphic and unattractive?

Distorted vertical and horizontal growth of the maxillomandibular skeleton in association with bimaxillary dental protrusion will result in both facial and dental disharmony.[84] This growth pattern may be associated with Class I, Class II, and Class III molar relationships, but it always occurs with mandibular and maxillary incisor procumbency and anterior open-bite malocclusion.[5,47,52,85,113,118] Individuals with bimaxillary dental protrusion will also have varying degrees of lip incompetence and mentalis strain; exposure of the anterior teeth in repose and gingival show with smile; and, typically, a dysmorphic chin in profile. If these aspects become excessive, then the diagnosis of an associated dentofacial disharmony is appropriate.[109]

The generally offered correction of the anterior open-bite malocclusion associated with bimaxillary dental protrusion is the extraction of four premolars followed by the orthodontic retraction of the anterior teeth into the edentulous gaps.[6,121,126] This treatment also tends to retract the lips and to reduce facial convexity.[33,34,48,72] To determine which individuals also have significant dentofacial (jaw) disharmony and thus will benefit from an orthognathic approach (i.e., the surgical repositioning of the upper and lower jaws), the clinician should assess pretreatment skeletal, dental, and soft-tissue parameters. This includes the following:

- An evaluation of the maxillomandibular skeleton (i.e., horizontal and vertical dimensions)
- An assessment of the dental condition (i.e., incisor inclination, spacing and crowding, the curve of Spee, arch width, overjet, and overbite)
- An evaluation of the soft-tissue static and dynamic position of the lips (i.e., the lip-to-tooth relationship in repose and with smile, the interlabial gap, the degree of mentalis strain with closure, and the nasolabial and labiomental angles).

Functional Aspects

- Wide lip separation with excessive effort required to achieve lip seal is present.
- Chronic obstructive nasal breathing as a result of increased intranasal airway resistance is frequent (see Chapter 10).
- Classic articulation errors in speech caused by the anterior open-bite malocclusion are expected (see Chapter 8).
- Chewing and swallowing difficulties as a result of the anterior open-bite malocclusion and lip incompetence are expected (see Chapter 8).
- Detrimental long-term effects on the dentition and the periodontium caused by traumatic occlusal forces, the spacing of the teeth in the alveolar housing, or previous camouflage orthodontic treatment may be seen (see Chapter 5 and 6).
- Temporomandibular disorder (TMD) should be looked for but is not generally problematic in these individuals (see Chapter 9).

Clinical Characteristics

- Separation of the lips at rest of >4 mm
- Excessive dental show with the upper lip at rest and excessive gingival show with a broad smile
- Flaccid lips with more effort required to bring them into closure (i.e., mentalis strain and lip incompetence)
- Excessive prominence of the lips with everted vermillion borders when viewed in profile
- Typically a mouth-breathing habit and an open-mouth posture with a protrusive tongue
- Convex maxillomandibular profile
- Chin deformity frequently seen in profile

Dental Findings

- Anterior open bite
- Maxillary and mandibular incisor proclination
- Exaggerated curve of Spee in the maxilla and a reverse curve in the mandible
- Frequently with narrow maxillary arch width
- Frequently with a Class II molar relationship, although a Class I or Class III malocclusion may be present
- Frequently with interdental spacing in the anterior dentition of the maxilla and mandible
- Despite incisor proclination, presence of adequate periodontal support without gingival recession, labial bone dehiscence, or fenestration is typical

Radiographic Findings

- Procumbency of the maxillary incisors
- Procumbency of the mandibular incisors
- Lack of chin prominence at the pogonion is generally notable

- Anterior open bite measured at the incisal edges
- Excessive lower anterior facial height (i.e., the distance measured from nasion to the pogonion)

Treatment Pitfalls

When considering orthognathic surgery for the individual with bimaxillary dental protrusion, there must be a compelling aesthetic or functional rationale for the shortening of the anterior vertical dimension of the face and the alteration of the horizontal projection (Figs. 24-1 through 24-11).[18,41,46,64,65,80,115] When present, facial aesthetic disharmony in association with bimaxillary dental protrusion is generally characterized by the following:

- *Excessive separation of the lips at rest (i.e., lip incompetence).* As a general rule, lip separation at rest should be less than 4 mm.
- *Excessive incisor show with the upper lip at rest.* As a general rule, more than 50% of the vertical height of the incisor should be seen to be considered excessive.
- *Excessive effort required to bring the lips into closure (i.e., mentalis strain).*
- *Significant vertical and horizontal facial disproportion when viewed in profile.*

All four characteristics are preferred to make the diagnosis of a significant dentofacial disharmony in association with bimaxillary dental protrusion to the extent that the surgical alteration of the facial height and facial projection through orthognathic surgery is recommended.

NOTE: An individual's degree of soft-tissue lip prominence may be independent of jaw and tooth position. The establishment of reasonable skeletal harmony and dental occlusion is not a guarantee of the achievement of preferred soft tissue lip shape and function.

When planning the orthognathic correction, a determination is made of how much incisor procumbency is too much.[96] Anterior teeth that protrude excessively are likely to be associated with lips that are prominent, everted, and separated at rest by more than 3 mm to 4 mm (i.e., lip incompetence). This will cause the individual to strain in an attempt to bring the lips together over the protruding teeth. Retracting (i.e., uprightening) the incisors with the successful closure of the open bite by whatever means tends to decrease facial convexity when the face is viewed in profile.[86,93,111,112,116] If the lips are prominent but are able to comfortably close over the teeth without excessive strain, then the lip posture (i.e., the position at rest) is largely independent of the current jaw and tooth position and more a result of lip muscle tone.[16,17,91,101,106,123] For such an individual, achieving correction of incisor procumbency and the open bite will have only a limited impact on lip function and prominence.[4,42,90,128]

Orthodontic Approach

Historical Perspective

During the early 1900s, the uncompromising non-extraction orthodontic approach set forth by Angle was the treatment of the day (see Chapter 2).[5] Angle used full-banded appliances to expand the arches as a method of bringing the teeth into ideal alignment, no matter how much additional protrusion was created in the process. Calvin Case disagreed with Angle's treatment concepts for the bimaxillary protrusive anterior open-bite problem and stated that *"one of the most dangerous features of the Angle classification is the universally applied teaching that when the dentures [teeth] are placed in normal occlusion, the facial outlines will take care of themselves."*[19] For the individual with bimaxillary dental protrusion, Case proposed bicuspid extraction in all four quadrants, followed by the placement of full-banded orthodontic appliances to retract the procumbent incisors into the extraction sites. It was not until well after Case's death that these techniques for orthodontic management were popularized by two of Angle's own students. Charles Tweed[124] in the United States and Raymond Begg[10] in Australia reintroduced extraction treatment into everyday orthodontic practice. The mainstay of treatment for dentoalveolar protrusion with anterior open bite continues to involve the removal of a premolar in each quadrant followed by orthodontic retraction of the protruded anterior teeth (see Chapter 17).[32,36,60,61,62,73,82]

Review of the Literature

There is a definite association between bimaxillary skeletal (jaw) disharmony and dentoalveolar (dental) protrusion with open bite. The standard treatment for the dentoalveolar aspects of this condition is four bicuspid extractions and then the use of maximum anchorage to orthodontically retract the anterior dentition to achieve space closure; this will also tend to decrease the chief complaint of lip fullness. The side effects of this form of treatment may include root resorption; excess lingual tipping of the anterior teeth; remodeling with dehiscence and fenestration of the cortical plate; insufficient retraction as a result of anchorage loss; and even more pronounced incisor exposure (i.e., gummy smile). Orthodontic technical maneuvers may also include the use of mini-screws as temporary anchorage devices (TADs), torque control of the upper and lower incisors, and alveolar corticotomies followed by more rapid orthodontic retraction into the bicuspid extraction sites.[7,21,22,55,56,59,69,71,78,83,87,89,92,125,127] These options also run the risk of the previously mentioned negative sequelae, but they are believed to shorten overall treatment time.

Text continued on p. 939

• **Figure 24-1** A 16-year-old girl was referred by her orthodontist for the evaluation of lip incompetence, anterior open bite, gummy smile, weak chin, and nasal obstruction. Orthodontics had previously been carried out without extraction therapy. The patient presented with a Class II anterior open bite dental protrusive malocclusion. A combined orthodontic and surgical approach was recommended. With non-extraction orthodontic decompensation complete, the patient's surgery included maxillary Le Fort I osteotomy in segments (arch expansion, correction of the curve of Spee, vertical intrusion, minimal horizontal advancement and counterclockwise rotation); sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

For a subgroup of individuals with bimaxillary dental protrusion, some clinicians find that there are advantages to an alternative surgical approach, including intraoperative first bicuspid extractions; the removal of associated alveolar bone; and anterior maxillary and mandibular segmental osteotomies with incisor uprightening and posterior repositioning. This approach should be compared with the classic mechanics of orthodontic retraction of the anterior teeth after extractions. Theoretic advantages of the anterior segmental dentoalveolar surgical approach include the ability to simultaneously reshape the pyriform rims and the anterior nasal spine region; alter the labiomental fold; and shorten the treatment time. Interestingly, in North America, the anterior segmental approach for the correction of bimaxillary dental protrusion has never gained traction. Unfortunately, neither approach (i.e., dentoalveolar segmental surgery or orthodontics only) will decrease an elongated lower facial height or improve a retrusive pogonion (i.e., neither approach will correct an associated jaw disharmony); doing so would require an orthognathic approach.

Iino and colleagues described a single case of bimaxillary dental protrusion (not associated with jaw disharmony) that was treated with corticotomy-facilitated orthodontics and titanium mini-plate anchorage devices (TADs).[54] The authors performed orthodontic treatment after multiple corticotomies and the placement of TADs for skeletal anchorage in an adult patient who desired a shortened treatment period. The patient had an Angle Class I molar occlusion with flaring of the maxillary and mandible incisors. Other findings included moderate dental crowding in both arches and a limited overbite relationship (i.e., a 5.5-mm

overjet and a 0.5-mm overbite). The upper and lower lips were protrusive with hypermentalis activity but without lip incompetence. The treatment rendered included the placement of TADs into the buccal alveolar bone of the maxilla for skeletal anchorage; the placement of edgewise appliances on the maxillary and mandibular teeth; maxillary first premolar and mandibular second premolar extractions; corticotomies on the lingual and buccal sides in the maxillary anterior and the mandibular anterior and posterior regions; and orthodontic leveling was initiated immediately after the corticotomies. The edgewise appliances were adjusted once every 2 weeks, and the total treatment time was 1 year. Cephalometric superimposition showed no anchorage loss in the maxilla and 2 mm of loss in the mandible. Panorex radiographs showed no reduction in crest bone height and no significant apical root resorption.

Baek and colleagues completed a study to investigate the differences in skeletal, dental, and soft-tissue results found among patients with bimaxillary dental protrusion who were undergoing either four bicuspid extractions with standard orthodontic retraction or four bicuspid extractions with anterior segmental osteotomies and repositioning.[8,9]

- The authors concluded that bimaxillary dental protrusion individuals with a significant associated dentofacial disharmony will not respond favorably to either of these approaches. Preoperative findings in the jaw disharmony subgroup included significant vertical and horizontal skeletal disproportion with specific pretreatment characteristics of skeletal Class II malocclusion; a poorly developed chin; and a measurably long vertical facial height. These individuals were found to require bimaxillary orthognathic surgery and were therefore excluded from the study.
- The authors concluded that individuals with isolated bimaxillary dental protrusion and anterior open bite (i.e., without associated dentofacial disharmony) who were treated with extractions and anterior segmental set-back osteotomies achieved less favorable facial aesthetics as compared with those patients who were treated with 4 bicuspid extractions and classic orthodontic mechanics.

Lee and colleagues analyzed the outcomes of the treatment of bimaxillary dental protrusion involving three different approaches.[70] The sample consisted of Korean adult female patients who presented with this condition (N = 65). None had yet received any orthodontic treatment or surgical procedures. These individuals were not felt to have significant vertical or horizontal skeletal disproportion of the jaws. Strict criteria for study inclusion were as follows: 1) Angle Class I molar relationship; 2) no significant anterior vertical facial discrepancy; 3) no significant anteroposterior skeletal discrepancy; 4) crowding of less than 3 mm; 5) Rickets aesthetic line to lower lip distance of more than 2 mm; (6) anterior incisal angle of less than 125 degrees; 7) chin point deviation of less than 3 mm; and 8) no symptoms of TMD.

The study patients were then divided into three treatment groups:

Group I (n = 29) was treated with four bicuspid extractions and conventional orthodontics to achieve maximum anchorage with a transpalatal arch, head gear, or both.
Group II (n = 20) was treated with four bicuspid extractions, corticotomy-assisted orthodontics, TADs in the maxilla, and anterior segmental (set-back) osteotomy in the mandible.
Group III (n = 16) was treated with four bicuspid extractions and anterior segmental (set-back) osteotomies in the maxilla and the mandible.

All lateral cephalometric radiographs were taken in centric relation and in the natural head position. Pretreatment and posttreatment lateral cephalograms were traced and digitized for analysis. The authors attempted to understand which specific individuals with bimaxillary dental protrusion did better with each of the three dentoalveolar treatment approaches. The authors concluded the following:

1. If a patient with bimaxillary dental protrusion does not have significant vertical or horizontal skeletal dysplasia and has a Class I molar relationship with proclined upper and lower incisors, then four bicuspid extractions and conventional orthodontic treatment can produce a good result.
2. If a patient with bimaxillary dental protrusion has relatively normal upper incisor inclination and a Class I molar skeletal pattern but markedly proclined mandibular incisors and poor chin development, then treatment with bicuspid extractions, anterior segmental osteotomy in the mandible, and conventional orthodontics in the maxilla will be a good option. This approach will reduce the lower lip protrusion without unwanted change of the upper incisor inclination.
3. If a patient with bimaxillary dental protrusion has severe proclination of the upper incisors, then four bicuspid extractions and corticotomy-assisted orthodontic treatment with the use of TADs will achieve maximum retraction and uprighting in the shortest treatment period and will generally produce good results.

Orthognathic and Dentoalveolar Surgical Approaches

If orthognathic surgery (i.e., Le Fort I down-fracture with segmentation and sagittal split ramus osteotomies of the mandible in combination with an osteotomy of the chin)

is undertaken to treat a significant associated dentofacial disharmony or if dentoalveolar surgery (i.e., anterior segmental osteotomies) is undertaken to manage bimaxillary dentoalveolar protrusion with anterior open bite (i.e., occlusal disharmony), then the surgical option selected should be in accordance with patient-specific facial characteristics and dental findings.[11-15,26,27,29,38,39,45,49,57,63,66,74,79,81,129] In this author's opinion, the dentoalveolar surgical approach has aesthetic advantages over the standard orthodontic approach for only a very specific subgroup of patients. A key point is that neither of these dentoalveolar approaches (i.e., segmental osteotomies versus orthodontics only) will reduce the anterior lower facial height; correct significant horizontal discrepancies; or alter chin height or projection. To accomplish these objectives, orthognathic surgery is required. Details of the individual's presenting dysmorphology are important when choosing either of the limited dentoalveolar forms of treatment (i.e., segmental osteotomies versus orthodontics only) or when selecting an orthognathic (jaw) approach.[20,23,97,105,108,130]

The orthognathic surgical correction of bimaxillary dental protrusion in association with excess vertical height and horizontal disproportion of the jaws should include maxillary Le Fort I osteotomy (often with segmentation) in combination with sagittal split ramus osteotomies of the mandible (see Chapter 15). This approach provides the flexibility needed to alter the maxilla and the mandible in all three dimensions (i.e., horizontal, vertical, and transverse). The maxilla will generally require anterior vertical shortening, transverse widening, correction of the curve of Spee, minimal horizontal advancement, and a degree of clockwise rotation. The mandible will generally require horizontal advancement and counterclockwise rotation. An osteotomy of the chin with minimal horizontal advancement is generally useful to further improve profile aesthetics and ease of lip closure. The simultaneous management of lifelong nasal obstruction may include septoplasty, inferior turbinate reduction, and recontouring of the nasal floor. This orthognathic and intranasal approach is carried out to achieve improved head and neck function (i.e., breathing, swallowing, chewing, speech, and lip competence) and to enhance facial aesthetics.[98,99]

Postsurgical Orthodontic Maintenance and Detailing

Managing the details of the in-hospital and at-home convalescence during initial healing after orthognathic surgery is essential for a successful outcome (see Chapter 11). Cephalometric and Panorex radiographs as well as facial and occlusal photographs are obtained at standard postoperative intervals to document healing. If segmental maxillary osteotomies were carried out, a prefabricated splint will have been secured to the occlusal surfaces during surgery. The orthodontist sees the patient within 24 hours of splint removal and replaces the maxillary sectional arch wires with a rigid continuous one (i.e., ≈5 weeks after surgery). The teeth are ligated together to maintain the arch form. The use of a transpalatal wire or a palatal acrylic plate may also be used to stabilize the arch form for several additional months if significant transverse expansion was carried out. Close orthodontic monitoring for skeletal and dental shifts and detailing during the first 6 months after surgery is essential.

Complications, Informed Consent, and Patient Education

The orthodontist and the surgeon are frequently asked to evaluate jaw disharmonies and malpositioned teeth and then to attempt to alter nature's events. With an understanding of the natural progression of the uncorrected bimaxillary dental protrusion associated with dentofacial disharmony and knowledge of how specific interventions will affect head and neck function and facial aesthetics, predictable results are generally achieved. Complications and patient dissatisfaction will always occur in a small percentage of individuals. The clinician's ability to communicate the potential risks, complications, alternative approaches, and benefits of the recommended treatment plan to the patient and the patient's family is essential to achieve a favorable result. When the patient, his or her family, and all treating clinicians are fully informed, shared responsibility for the treatment outcome is more likely (see Chapter 16).

Malocclusion after Orthodontics and Orthognathic Surgery

There are inherent biologic challenges to the orthodontic movement of the teeth in the alveolar process and to the surgical repositioning of the jaws or jaw segments in the individual with bimaxillary dental protrusion and an associated dentofacial disharmony.[51,102,110,114,117] This includes the technical aspects of the repositioning; the initial healing requirements; and the difficulties associated with the long-term maintenance of the mechanically relocated teeth, jaws, and jaw segments. By following sound biomechanical and facial aesthetic principles, clinicians are able to carry out orthodontic treatment and surgical procedures and to effectively maintain the results in most cases. Potential intraoperative technical difficulties associated with sagittal split ramus osteotomies of the mandible and maxillary Le Fort I osteotomies can result in immediate (early) malocclusion, but this is generally preventable (see Chapter 17). Timing the surgery to limit ongoing mandibular growth from occurring afterward is usually possible (see Chapter 17). Condylar resorption after orthognathic surgery is rarely seen in the patient with bimaxillary dental protrusion (see Chapter 36). All of these factors must be taken

into account to best achieve and then maintain the desired result.

Temporomandibular Disorders: The Effects of Orthodontics and Orthognathic Surgery

It is estimated that an average of 32% of the population reports at least one symptom of TMD, whereas an average of 55% of the population demonstrates at least one clinical sign of the condition. TMD includes various symptoms and signs that involve the temporomandibular joint, the masticatory muscles, and the related structures. The symptoms and signs may include a spectrum of referred head and neck pain; joint noise (i.e., popping, clicking, or crepitus); reduced or altered mandibular movements as a result of muscle spasm or disc displacement with or without reduction; condylar head erosion; and pain during the direct palpation of either of the temporomandibular joints or the masticatory muscles. Occlusal factors (i.e., degrees of malocclusion) are often claimed to be associated with TMD. Interestingly, the correction of a skeletal anterior open bite through orthodontics and orthognathic surgery is likely to relieve symptoms and signs of TMD; however, this is not predictable for each individual patient (see Chapter 9).[1]

Conclusions

Bimaxillary dental protrusion is characterized by the proclination of the anterior maxillary and mandibular dentition with an open-bite malocclusion. The correction of the dental disharmony in most individuals is carried out with the extraction of four premolars and conventional orthodontic incisor retraction and uprighting. An alternative approach, which is preferred in only limited and specific circumstances, involves the combination of four bicuspid extractions and anterior maxillomandibular segmental osteotomies with set-back. This dentoalveolar surgical approach may shorten the treatment time, but subtle differences in the expected aesthetic results and the potential for complications must be considered.

In the patient with bimaxillary dental protrusion, facial characteristics associated with significant skeletal disharmony include the following: excessive separation of the lips at rest and effort required to bring the lips into closure; excessive incisor show when the upper lip is at rest and gingiva show with smile; and significant vertical and horizontal facial disproportion. If these skeletal findings are present, then orthognathic surgery will be required to maximize head and neck function and to enhance facial aesthetics.

- Temporomandibular Disorders: Effects of Orthodontics and Orthognathic Surgery
- Special Wound Healing Risk Factors
- Comprehensive Dental Rehabilitation
- Unique Orthodontic Treatment Considerations
- Previous Suboptimal Facial Surgery
- Facial Aging and Rejuvenation
- Recovery for the Adult after Orthognathic Surgery
- Conclusions

The techniques for the correction of a dentofacial deformity are basically the same for the middle-aged adult as they are for the teenager and the young adult. To achieve a favorable result in the adult orthognathic patient, it is essential to recognize age-related treatment pitfalls such as medical risk factors; progressive upper airway dysfunction; dental rehabilitation needs, including periodontal and restorative aspects; the effects of facial soft-tissue aging; and the often prolonged physiologic and psychosocial responses to surgery (Figs. 25-1 through 25-11).

Special Medical Considerations

For the adult who is more than 40 years old and who is considering orthognathic surgery, additional medical risk factors may include cardiovascular disease; the effects of obesity; smoking history and pulmonary function; the potential for deep vein thrombosis or pulmonary embolus; the effects of bisphosphonate medication on wound healing; and occult malignancy. As with teenagers and young adults, taking a thorough history, performing a review of the medical records, and completing a physical examination are essential. To clarify areas of concern in these patients, there should be emphasis placed on the need for a thorough clearance examination by a primary care physician; evaluations by other medical specialists; (e.g., cardiologist, pulmonologist); the completion of an electrocardiogram, chest radiography, and laboratory tests (e.g., chemistries, hematology, thyroid tests, coagulation tests); and other special studies (e.g., stress test, echocardiogram, sleep study, pulmonary function tests). Obtaining a hemoglobin A1C level and a serum or urine cotinine level are useful checks to address long-term diabetes effects and smoking compliance, respectively. The adult with a dentofacial deformity and an elevated body mass index is at risk for obstructive sleep apnea (OSA) and therefore more vulnerable to intraoperative and postoperative complications (see Chapter 26).

Functional Assessment of Head and Neck Structures

The orthognathic surgeon should evaluate the baseline head and neck functions of their patients, which include speech, swallowing, chewing, breathing, hearing, vision, cognition, and psychosocial competence (see Chapters 7 and 8). The documentation of cervical spine and temporomandibular joint (TMJ) baseline function and of any limitations in neck or mandibular range of motion is also essential (see Chapter 9). Each of these aspects may be negatively affected by the presenting maxillofacial malformations and influenced favorably or unfavorably by the treatment being contemplated. Baseline chronic obstructive nasal breathing as a result of septal deviation, enlarged inferior turbinates, or a tight nasal aperture should not be ignored (see Chapter 10).[103,104,106,107] In the adult, weight gain with adipose hypertrophy within the upper airway in combination with

Text continued on p. 981

• **Figure 25-1** A woman in her mid 50s was referred by her general dentist to an orthodontist for the management of a longstanding Class II excess overjet malocclusion that had gradually resulted in the deterioration of the posterior dentition. The orthodontist recognized that the malocclusion resulted from a retrusive mandible and a constricted maxilla. With referral for surgical evaluation, a head and neck examination was completed. In addition to a developmental jaw deformity that involved both the maxilla and mandible, chronic obstructive nasal breathing and a sleep history consistent with obstructive sleep apnea was clarified. Suboptimal facial aging with a desire for an improved neck–chin angle was also discussed. An attended polysomnogram confirmed moderate obstructive sleep apnea. The patient agreed to proceed with orthodontics, including lower first bicuspid extractions to relieve dental compensation in combination with jaw and intranasal surgery. The objectives were to improve the airway, to enhance facial aesthetics, and to achieve improved long-term dental health. The patient's surgical procedures included maxillary Le Fort I osteotomy in segments (horizontal advancement, counterclockwise rotation, arch expansion, and the correction of the curve of Spee); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement); an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication); and septoplasty and inferior turbinate reduction. **A,** Facial views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Profile views before and after reconstruction. Note the improved A-point to B-point relationship.

Note the improved posterior airway space documented.

• **Figure 25-2** A woman in her early 50s was referred by a prosthodontist for surgical evaluation. There had been a gradual deterioration of her dentition that was at least partially a result of the longstanding Class II excess overjet deep-bite malocclusion. The head and neck evaluation confirmed a retrusive mandible, which also resulted in retroglossal airway obstruction. A desire for improved profile aesthetics was also discussed. A comprehensive approach to dental rehabilitation, improvement of the upper airway, and facial rejuvenation/reconstruction was chosen. Coordinated endodontic, orthodontic, periodontic, prosthodontic, and surgical care was required. Periodontal treatment, extractions, dental implant placement, restorative temporization, and orthodontic alignment were carried out. This was followed by surgery that included bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical lengthening) with interpositional grafting; and an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication). This was followed by crown lengthening and then by the final dental restorations. **A,** Frontal views before and after reconstruction/dental rehabilitation. **B,** Facial oblique views before and after reconstruction/dental rehabilitation. **C,** Profile views before and after reconstruction/dental rehabilitation.

Prior to treatment

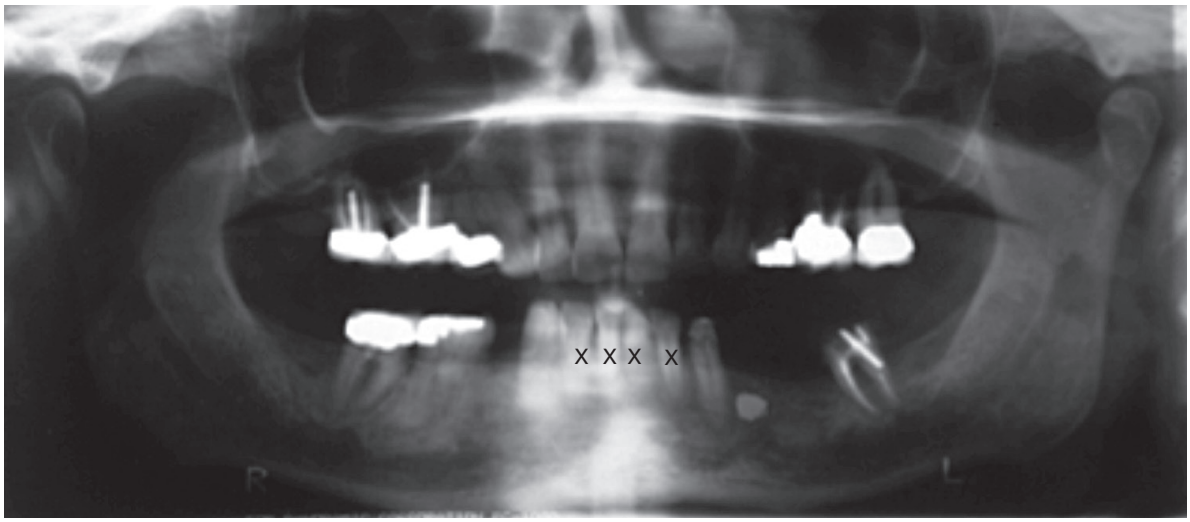
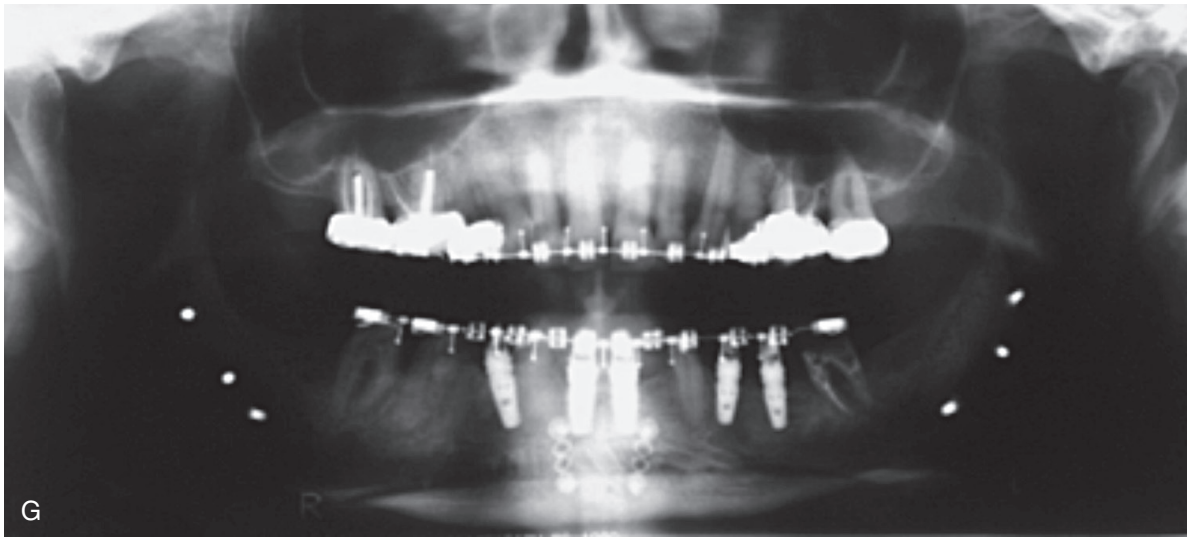
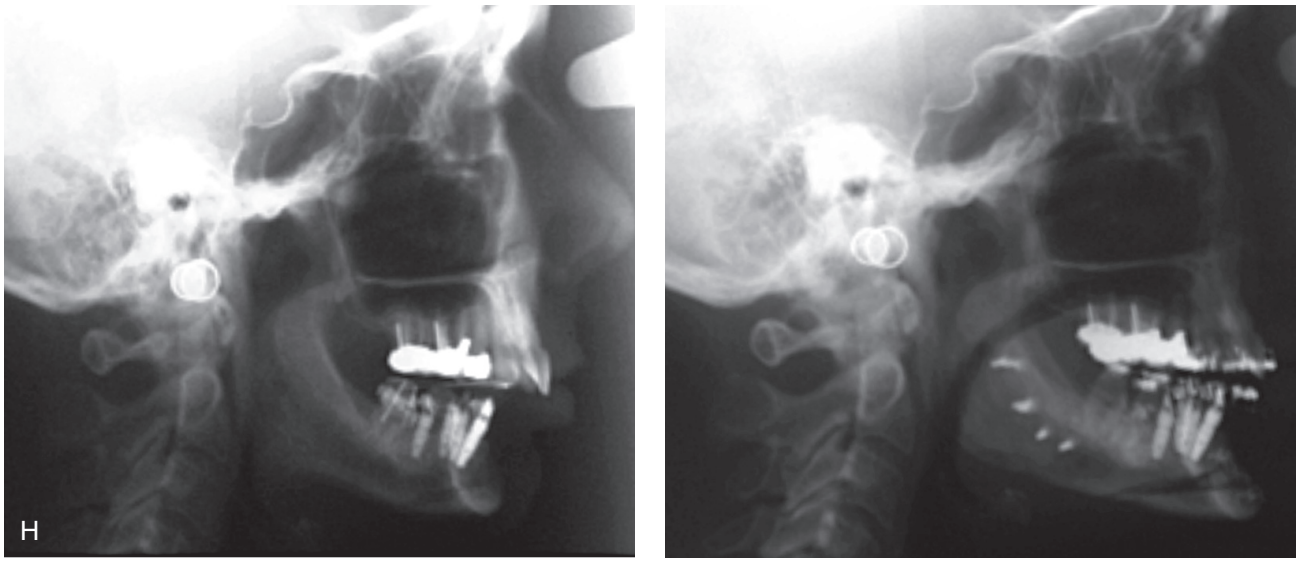
• **Figure 25-2, cont'd E,** Articulated dental casts that indicate analytic model planning. **F,** Profile view of the chin. The intraoperative view of the chin osteotomy indicates vertical lengthening with hydroxyapatite interpositional bloc graft.







• **Figure 25-2, cont'd G,** Panorex radiographs before and after lower jaw and chin surgery with the placement of dental implants. **H,** Lateral cephalometric radiographs before and after reconstruction.

• **Figure 25-3** A woman in her late 40s with a long face growth pattern suffered deterioration of the dentition. Her periodontal risk factors included inadequate attached gingiva; dental root crowding within limited alveolar bone support, nasal airway obstruction with forced mouth breathing, and lip incompetence with drying of the exposed gingiva. An attended polysomnogram confirmed obstructive sleep apnea. Unfavorable soft-tissue envelope distortions and premature facial aging were also present. She agreed to a comprehensive surgical and dental rehabilitative approach. Periodontal treatment was followed by restorative temporization and orthodontic alignment, including four first bicuspid extractions. This was followed by surgery that included maxillary Le Fort I osteotomy in segments (vertical shortening, horizontal advancement, transverse widening, and limited clockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and limited counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

• **Figure 25-3, cont'd C,** Oblique facial views before and after treatment. **D,** Profile views before and after treatment. Note the pretreatment tendency for the patient to hyperextend her neck to achieve an improved airway. After successful surgery and with improved daytime breathing, her neck rests in a natural (neutral) position.

• **Figure 25-4** A woman in her mid 50s was experiencing significant dental deterioration as a result of occlusal trauma. An orthodontic consultation followed by surgical evaluation was carried out. The longstanding developmental jaw deformity was characterized by a short face growth pattern in combination with maxillary transverse constriction. There was a Class II deep-bite excess overjet malocclusion. The patient's head and neck evaluation confirmed a lifelong history of obstructed nasal breathing, restless sleeping at night, and a degree of daytime fatigue that was consistent with obstructive sleep apnea. Unfavorable facial aging that is typical of maxillomandibular deficiency was recognized. A comprehensive surgical and dental rehabilitative approach was selected. The objectives included dental rehabilitation, the enhancement of facial aesthetics, and an improved airway. The patient's procedures included maxillary Le Fort I osteotomy in segments (horizontal advancement, vertical lengthening, and arch expansion); bilateral sagittal split ramus osteotomies (horizontal advancement); osseous genioplasty (vertical lengthening and horizontal advancement); an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication); and septoplasty and inferior turbinate reduction. **A,** Frontal views in repose before and after reconstruction/dental rehabilitation. **B,** Frontal views with smile before and after reconstruction/dental rehabilitation.

• **Figure 25-5** A woman in her early 40s wished to correct her malocclusion and improve her smile. She was referred to an orthodontist who then requested surgical evaluation. She was found to have a long face growth pattern and a lifelong history of obstructed nasal breathing. There was dental crowding in each arch, mild gingival recession associated with the posterior dentition, and a Class II anterior open-bite malocclusion. The patient was aware of unfavorable facial aesthetics, which included a retrusive chin and an obtuse neck–chin angle. She agreed to a comprehensive surgical and dental rehabilitative approach. She underwent extraction of four bicuspids, orthodontic alignment, and then surgery. The patient's procedures included Le Fort I osteotomy (vertical intrusion, horizontal advancement, and counterclockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); an anterior approach to the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 25-5, cont'd F,** Articulated dental casts that indicate analytic model planning. **G,** Lateral cephalometric radiographs before and after surgery.

• **Figure 25-6** A woman in her early 50s arrived for surgical evaluation and requested facial rejuvenation. Her head and neck examination confirmed a lifelong history of obstructed nasal breathing and a long face growth pattern with gummy smile and lip incompetence. Unfavorable soft-tissue envelope facial aging added to the original dentofacial deformity. Early during her life, posterior occlusal equilibration was carried out to close down the anterior open bite; this resulted in dental deterioration that required crowns in the posterior dentition and the need for root canal therapy in many of the teeth. At this time, the patient agreed to a combined surgical and dental rehabilitation approach. After orthodontic preparation, the patient's surgical procedures included maxillary Le Fort I osteotomy (vertical intrusion, horizontal advancement, and counterclockwise rotation); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal recontouring. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

• **Figure 25-7** A woman in her mid 50s was seen by a prosthodontist for the management of a deteriorating posterior dentition. She was confirmed to have secondary dental trauma as a result of a longstanding malocclusion. She was referred to an orthodontist and then for surgical assessment. Her head and neck evaluation confirmed a short face growth pattern with a Class II excess overjet deep-bite constricted maxillary arch malocclusion. There was a lifelong history of obstructed nasal breathing and the suggestion of obstructive sleep apnea, which was confirmed with an attended polysomnogram. Facial aesthetic concerns included the downturned corners of the mouth, the deep perioral creases, the early jowl formation, the weak profile, the obtuse neck–chin angle, and the loose skin of the neck. The patient agreed to a comprehensive surgical and dental rehabilitative approach. Periodontal evaluation, initial restorations, and orthodontic decompensation preceded surgery. The patient's surgical procedures included maxillary Le Fort I osteotomy (horizontal advancement, counterclockwise rotation, and vertical adjustment); bilateral sagittal split osteotomies of the mandible (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement); an anterior approach to the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication); and septoplasty, inferior turbinate reduction, and nasal recontouring. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

• **Figure 25-8** A woman in her mid 30s was referred by an orthodontist for surgical evaluation. She had a lifelong history of obstructed nasal breathing and a long face growth pattern. Throughout her middle childhood and teenage years, she had undergone attempted growth modification followed by orthodontic camouflage that included four bicuspid extractions in an effort to neutralize the occlusion. This resulted in periodontal deterioration and dental relapse with residual malocclusion. She now agreed to a comprehensive surgical and dental rehabilitative approach. Periodontal treatment was followed by orthodontic decompensation. The patient's surgery included maxillary Le Fort I osteotomy in segments (horizontal advancement, vertical shortening, counterclockwise rotation, arch expansion, and the correction of the curve of Spee); bilateral sagittal split ramus osteotomies in segments (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical reduction and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal recontouring. **A,** Frontal views in repose before and after reconstruction/dental rehabilitation. **B,** Frontal views with smile before and after reconstruction/dental rehabilitation.

• **Figure 25-11** An Asian woman in her mid 30s had a developmental jaw deformity that was characterized by maxillary deficiency and relative mandibular excess. In the childhood years, she had been treated with growth modification followed by four bicuspid extractions and orthodontic camouflage mechanics. Periodontal deterioration resulted, and malocclusion remained. She also had a lifelong history of obstructed nasal breathing. She now agreed to a comprehensive surgical and dental rehabilitative approach. Periodontal treatment was followed by orthodontic decompensation. The patient's surgery included maxillary Le Fort I osteotomy in segments (horizontal advancement, vertical intrusion, counterclockwise rotation and transverse widening); bilateral sagittal split ramus osteotomies (horizontal advancement); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views with smile before and after treatment. **B,** Oblique facial views before and after treatment. **C,** Profile views before and after treatment.

hypotonia of the pharyngeal muscles in the presence of an uncorrected dentofacial deformity is likely to result in OSA. A formal attended polysomnogram, a complete upper airway evaluation, and a consultation with a sleep specialist are frequently indicated (see Chapter 26).

Temporomandibular Disorders: Effects of Orthodontics and Orthognathic Surgery

It is estimated that an average of 32% of the population report at least one symptom of temporomandibular disorder (TMD) and that an average of 55% demonstrate at least one clinical sign of such a condition.[117] TMDs include various symptoms and signs of the TMJs, the masticatory muscles, and the related structures. The symptoms and signs may include a spectrum of referred head and neck discomforts; joint noise (e.g., popping, clicking, crepitus); reduced or altered mandibular movements as a result of muscle spasm or disc displacement with or without reduction; condylar head erosion; and pain on direct palpation of either TMJ or of the masticatory muscles.

The effects of orthodontics and orthognathic surgery on TMJ function for each specific adult patient cannot be fully predicted. Many clinical studies report improvement in TMJ symptoms and signs in a majority of individuals after successful orthodontics and orthognathic surgery, although some patients will deteriorate after the procedures. The favorable TMJ effects of orthognathic surgery often observed in patients with preoperative TMD may be the result of the improved occlusion, the restoration of normal facial height and jaw projection, or the reduced emotional stress. Adults with longstanding TMD should be cautioned that their pretreatment findings may not respond to occlusal correction and jaw-straightening surgery. Baseline TMD

problems in the patient with a dentofacial may primarily be masticatory muscle disorders (i.e., myofascial conditions) or, less commonly, the result of joint pathology (i.e., internal derangement). These two problems may coexist, and the distinction in some individuals may be difficult. It is unlikely that the correction of an existing dentofacial deformity will correct either internal joint problems or other non-muscular sources of pain. Myofascial pain develops when muscles are fatigued, because they then tend to go into spasm. Myofascial pain generally occurs after clenching or grinding the teeth for many hours each day, presumably as a response to stress. It is also true that some types of occlusal discrepancies predispose the individual who clenches or grinds his or her teeth to TMD. A compelling argument against malocclusion as the primary cause of TMD is the observation that TMD is not more prevalent among individuals with malocclusion as compared with those with a more normal occlusion. Interestingly, for those individuals with myofascial pain, the orthodontic mechanics required as part of the orthognathic correction are often helpful. This is because orthodontic treatment makes the teeth sensitive, which tends to limit grinding and clenching. Therefore, when the parafunctional (i.e. clenching, grinding) activity stops, the myofascial pain is often diminished. The changing occlusal relationships during the orthodontic phase of treatment may also contribute to a break in the cycle that contributed to the initial muscle fatigue and pain. The cycle of clenching and grinding is also broken during the healing phase that takes place just after orthognathic surgery. Unfortunately, it is also recognized that, at some point after successful orthodontics and orthognathic surgery, the individual with a long history of myofascial TMD symptoms may return to the clenching and grinding parafunctional habits. The use of an intra-occlusal splint in this situation will often be the best way to break the cycle and keep symptoms at bay. For all of these reasons, the individual's rationale for the correction of the jaw deformity and the associated malocclusion should not be solely based on a desire for the permanent relief of TMJ symptoms and signs (see Chapters 7 and 9).

Special Wound Healing Risk Factors

Special wound healing risk factors may include previous radiation therapy, diabetes mellitus, smoking or other forms of nicotine use, and past or current bisphosphonate treatment for osteoporosis. Diabetes mellitus, high blood pressure, hyperlipidemia, and OSA are frequent comorbidities of obesity that may complicate wound healing. A significant incidence of postoperative infections among diabetic patients undergoing maxillary or mandibular osteotomies has been reported, despite adequately controlled glucose levels. The inhalation of nicotine via cigarette smoke affects pulmonary function as well as tissue oxygenation and the healing of the surgical wounds. Smoking (nicotine ingestion) has been shown to delay the chondrogenic phase of bone (osteotomy) healing, thereby negatively affecting the circulation of elevated flaps and their healing after wound closure. It is known that bisphosphonate treatment for osteoporosis affects osteoclastic activity and may negatively affect bone healing (see Chapter 16).

Comprehensive Dental Rehabilitation

Recognizing when a patient who is seeking orthognathic surgery has additional dental needs beyond standard orthodontics is essential to the achievement of a favorable outcome (see Figs. 25-1 through 25-11). The need for periodontal evaluation and treatment as well as the need for complex dental restorative work should be considered for every adult patient before the initiation of a coordinated orthodontic and jaw surgical approach. This is especially true for the adult who has suffered dental and periodontal sequelae from a longstanding uncorrected dentofacial deformity and who may have undergone camouflage treatment in an attempt to neutralize the occlusion (e.g., orthodontics, occlusal equilibration, restorative dentistry). The American Board of Orthodontics now requires evidence of the pretreatment periodontal condition for all adult patients.[49] Proceeding with surgical and orthodontic management in an adult without considering a comprehensive dental rehabilitation plan is discouraged and only undertaken with full disclosure to the patient and discussion among the treating clinicians (see Chapters 6 and 16).

Unique Orthodontic Treatment Considerations

There has been a continuous increase in the number of adults seeking orthodontic treatment in North America as well as throughout Europe, South America, and the Asian countries. There is a worldwide increase in facial aesthetic awareness and a desire to maintain the dentition throughout life. The orthodontic movement of teeth in adults has potential effects on the periodontium that depend on the level of orthodontic force; the adequacy of alveolar bone and mucogingival tissue; and the presence of active periodontal disease (see Chapters 5 and 6). With aging, there may be progressive change of the periodontium with an increase in the crown-to-root ratio; a decrease in the resistance to spontaneous tooth migration; and a change in the center of resistance of periodontally affected teeth. The initial response of the periodontal ligament and the alveolar bone to orthodontic loading in the adult may be delayed; however, after tooth displacement has started, it can be carried out in the same way as it is for a teenager or a young adult. Although there is no known age limit to the orthodontic movement of teeth, the periodontium should be healthy when tooth movement is initiated.

As compared with a teenager, a middle-aged adult (i.e., someone >40 years old) with an uncorrected jaw deformity often requests a timely solution to his or her jaw, dental, and airway problems. Interestingly, the anticipation of an extended orthodontic treatment timeframe may be this

patient's greatest personal deterrent to proceeding. The adult is also more likely to present with advanced periodontal disease; dental migration and defective areas; traumatic occlusal problems; dental ankylosis; and the presence of fixed dental elements (e.g., titanium implants). These factors, by definition, will alter orthodontic mechanics. Contemporary orthodontic now offers a spectrum of options to improve the efficiency of treatment, including the use of light continuous forces; computer-aided design of orthodontic devices (e.g., Sure Smile, Insignia); and the regional acceleratory phenomena as described by Wilko and Wilko (see Chapter 5). These options must be viewed in light of their potential risks, complications, and costs (see Chapter 5).

Previous Suboptimal Facial Surgery

It is not uncommon to see an adult with an uncorrected dentofacial deformity who has undergone facial cosmetic procedures in an attempt to camouflage aesthetic concerns.[4,31,132-136] In the individual with an uncorrected jaw deformity, the most commonly seen camouflage procedures include reduction rhinoplasty; a chin implant; cheek implants; and, to a lesser degree, angle of the mandible or perinasal implants.[13,27,34,46,59,79,87,88,110,111,129,137,139] Autogenous and allogenic soft-tissue fillers and Botox injections (e.g., to lower the upper lip and to decrease a gummy smile) are also frequently tried.

A *rhinoplasty* carried out in the patient with an uncorrected jaw deformity patient is often over-reduced in an attempt to "shrink" the nose. This is most frequently seen in association with a horizontally retrusive lower face (e.g., short face growth pattern, long face growth pattern, isolated mandibular deficiency; see Chapters 19, 21, and 23). There may have been over-reduction of the nasal dorsum (i.e., bone and cartilage), over-resection of the lower lateral cartilages, and excess narrowing of the nasal base (i.e., Weir excisions; see Chapter 38). A reduction in nasal airflow as a result of the collapse of the internal or external nasal valves may have been an unanticipated side effect (see Chapter 10).

A *chin implant* placed in the patient with a mandibular deficiency often adds excess horizontal projection without addressing the vertical deformity; this will result in a deepened labiomental crease and an overly prominent pogonion (see Chapter 37). In the individual with a long face Class II open-bite growth pattern, the placement of a standard chin implant (i.e., without shortening the vertical chin height) further increases mentalis strain. Resorption of the bone below the implant and excess stretching of the overlying soft tissues with capsule formation may also occur. This is more frequently seen with the use of non-porous implant materials (e.g., Silastic) and when the implant is not secured in a stable manner (e.g., screw fixation) to the underlying bone (see Chapter 37). These failed camouflage surgical procedures further complicate plans for an anatomic reconstruction and effective facial rejuvenation.

Facial Aging and Rejuvenation

Background

The visual appearance of facial aging may be affected by all tissue layers and cell types, including the surface layer of the skin; the subcutaneous tissue; the superficial and deep mimetic muscles and the investing fascia (i.e., the submuscular aponeurotic system); the superficial and deep adipose tissue; and the retaining ligaments that connect the soft tissues to the skeleton and that separate them into compartments.[10,14,18,67,85,90,114] Although facial aging is visualized through the soft-tissue envelope, it is profoundly affected by the underlying maxillomandibular skeletal structures. Soft-tissue facial rejuvenation procedures generally focus on the following:

1. *The elevation, redraping, and excision of the skin, the subcutaneous tissue, and the submuscular aponeurotic system and platysma layer.* This is to correct gravitational (descent) changes that have occurred over time.
2. *The management of the volumetric changes of adipose tissue that occur with age.* This includes compartment-specific depletion (deflation), hypertrophy (expansion) of the fat cells, and stretching of the retaining ligaments that then affect the facial contours and curvatures.*
3. *The management of the surface layer of the skin.* This layer is affected by both hereditary (genetic) and environmental factors (e.g., chronic exposure to strong ultraviolet light, nicotine/cigarette smoke, dehydration, nutritional deficiencies, temperature extremes, traumatic influences).[15,16,20,23,45,72,78,93,138]
4. *The consideration of expressive muscle alteration with age (i.e., the "facial recurve" concept).* Ligamental relaxation may be a prominent component of facial aging. For example, it may be responsible for malar descent in the midface. In the nasal region, "tip drooping" may be caused by ligament loosening of the lower lateral cartilage and clockwise rotation of the columella.[124]

An important morphologic fact is that, *in the presence of a baseline uncorrected developmental dentofacial deformity, the overlying soft-tissue envelope will be distorted and less attractive* (see Figs. 25-1 through 25-11).[103,115,145] The long-standing skeletal dysmorphology will likely be responsible for a majority of the patient's concerns about premature and unfavorable facial aging. An example of this phenomenon is seen in patients with the short face growth pattern (see Chapter 23). With age, the decreased lower anterior facial height and the diminished horizontal projection associated with this condition result in the premature loss of a

*References 3, 21, 29, 30, 32, 50, 61, 64, 65, 73-77, 81, 82, 86, 122, 123, 131

youthful appearance (see Fig. 40-1). There will be accentuated perioral creases (i.e., marionette lines), early and excessive jowl formation, loose skin in the neck (i.e., a "turkey gobble" appearance), and a further worsening of the already deficient neck–jaw angle. Reconstruction of this pattern of dentofacial deformity in the adult to reflect Euclidean proportions is likely to have a profound rejuvenating effect (see Chapter 23).

The usual modus operandi of the cosmetic surgeon who has been asked to manage facial aging in the individual with a baseline dentofacial deformity involves neck and cheek soft-tissue flap undermining, redraping, and then the excision of skin that is under tension in the horizontal and vertical planes; this is also known as a *face lift.*[5,6,8,52,53,56,57,83,108,125,128,130] Augmentation implants may be considered and occasionally placed (e.g., the chin, the angle of the mandible, the cheek, the pyriform rim) in an attempt to modify underlying skeletal deficiencies.[13,27,34,46,59,60,79,87,88,137,139] In most cases, this approach predictably makes the face look different but not youthful or attractive. A natural-appearing rejuvenation in the adult with a dentofacial deformity requires reconstructing the normal curves and contours to the skeleton; these changes will then be favorably reflected in the overlying soft-tissue envelope. This is most naturally accomplished through orthognathic procedures that restore Euclidian proportions to the maxillomandibular complex.[22,44,103,105,112,113,115,118]

It is also true that facial aging—even in the presence of a proportionate skeleton—tends to gradually result in a transition from a heart-shaped face to a rectangular and then a pear-shaped face as gravity-induced descent and anterior drift of the soft-tissue envelope occur from the malar region superiorly through the nasolabial fold and from the submalar region to the jowls. At some point, as the individual ages, ideal rejuvenation is likely to require restoration of the lax and altered soft-tissue envelope, possibly via a brow lift, an eye lift, and a face lift. Fat volume redistribution frequently occurs with age (e.g., atrophy, hypertrophy) and may also benefit from rejuvenation procedures.[3,21,29,30,32,50,61,64,65,73,77,81,82,86] The surface layer of the skin may have weathered with age and be improved with quality skin care or resurfacing procedures (e.g., chemical peels, laser treatments, dermabrasion; see Chapter 40).[15,16,20,23,45,72,78,93,138]

The term *reconstruct* can be defined as "to bring to normal." The term *rejuvenate* means "to restore the look of the individual at a younger age." In the adult with a baseline dentofacial deformity, the creation of normal facial curvatures—first through skeletal reconstruction and then via soft-tissue rejuvenation procedures—is required to fully capture the appearance of health, vitality and beauty. If successful, the enhancement of facial appearance will be immediately obvious for all to see without the need for quantitative analytic assessment. The maxillofacial surgeon has a unique opportunity to reconstruct the skeletal structures and to rejuvenate the soft tissues of the adult with an uncorrected dentofacial deformity. Attention is also focused on the rehabilitation of the dentition and the periodontium and on the achievement of a more functional upper airway. Adults with dentofacial deformities who undergo successful orthognathic surgery will experience a quantum change: they will look younger and better as compared with how they looked earlier during their lives. A variety of reactions from the patient's social network are to be expected; these will range from positive responses to surprise, bewilderment, and even resentment. The individual's response to these initial reactions will depend on his or her personality type, preoperative preparation, and inner ego stability (see Chapter 7).

Periorbital and Midface Aging

Most cosmetic surgeons focus on the soft tissues when they are considering options for the management of periorbital and midface aging.[1,2,9,19,24,26,33,39,42,51,54,55,119] The traditional approach to aging in this region of the face focuses on the management of the laxity of the soft-tissue envelope and the reduction of protruding lower eyelid fat bags.[40,47,80,116] The spectrum of current theories of periorbital and midface aging as well as methods of management are varied and have strong advocates, including the following.

1. **Lambros** has demonstrated through longitudinal photographic imaging that descent probably does not have as large a role in the aging process as previously thought.[66]
2. **Coleman** believes that the role of fat atrophy with volume loss and secondary sagging of the soft-tissue envelope is critical.[25]
3. **Gosain** evaluated changes in the cheek fat pad with aging through magnetic resonance imaging and found a combination of hypertrophy and ptosis (rather than atrophy) to be an important factor.[48,150-152]
4. **Le Louarn** postulates that the facial mimetic muscles are a predominant cause of the visual appearance of aging in the midface. He believes that repeated motion (i.e., contraction) of these muscles results in the redistribution of the facial fat over time, which eventually creates the aged face.[69]
5. **Jelks** has drawn attention to the importance of the anatomic relationship between the ocular globe, the periorbital soft tissues, and the underlying skeleton with respect to midface aging.[62,63] A positive relationship (i.e., a positive vector) is said to exist when the most anterior projection of the globe in profile lies behind the lower eyelid margin.[91] A negative relationship (i.e., a negative vector) exists when the most anterior projection the globe in profile lies anterior to the lower lid. Individuals with a negative vector relationship are more likely to have scleral show, to exhibit an apparent loss of cheek prominence, and to have a deep nasojugal groove. They are also prone to suboptimal results if traditional soft-tissue eyelid rejuvenation procedures are carried out. To achieve the most favorable result, the underlying skeletal defi-

ciency and the lower lid laxity (i.e., lateral canthopexy) should also be addressed.

6. **Pessa and colleagues** agree with Jelks that skeletal deficiency is responsible for the negative vector relationship documented in adults with unattractive periorbital and midface aging.[95-101] These authors postulate that, with age, the infraorbital rims partially resorb and regress posterior relative to the cornea. They also believe that, with age, the upper aspect of the anterior maxilla is partially resorbed with progressive curve distortion (i.e., concavity). They infer that, to achieve the most favorable result, the underlying skeletal deficiency must be addressed.
7. In his analysis of periorbital and midface aging, **Yaremchuk** agrees with Jelks and Pessa that the negative affects of aging in the periorbital midface region are greatly influenced by the underlying skeleton.[140-149] He believes that a key element for attractive midface rejuvenation is reconstructing the skeleton to achieve convexity and a positive vector relationship. He accomplishes this via augmentation of the zygoma, the infraorbital rim, the anterior maxilla, and the base of the nose, as indicated. He frequently combines skeletal enhancement with lower lid and midface soft-tissue suspension to create and restore youthful and attractive periorbital aesthetics.

NOTE: This author believes that horizontal (sagittal) deficiency of the anterior maxilla—rather than a lack of projection of the zygomatic complex or of the infraorbital rims per se—is a frequent cause of the observed negative-vector eyelid relationship originally described by Jelks.

Maxillary horizontal (sagittal) deficiency that has been present since the teenage years is a frequent cause of the observed negative vector and results in an unattractive midface and lower eyelid appearance that worsens with age. Exceptions may include individuals of Asian decent with a hereditary tendency for excess bizygomatic width and limited zygomatic buttress projection. These individuals are more likely to benefit from zygomatic buttress (sagittal) augmentation to achieve aesthetic advantages.

A critical review of the literature provides little convincing evidence to support the theory put forth by Pessa and colleagues regarding a progressive deterioration or resorption of the infraorbital rim, the zygoma, or the anterior maxilla with advancing age in humans. The more logical explanation for the observed negative vector in some individuals is the presence of a developmental skeletal deformity that changes little after the teenage years (i.e., after skeletal maturity is reached). The common developmental jaw deformities with which maxillary horizontal (sagittal) deficiency is seen include: the long face growth pattern; maxillary deficiency with relative mandibular excess; maxillomandibular deficiency (i.e., the short face growth pattern); and cleft maxillary hypoplasia.

In the past, many cosmetic surgeons have not paid enough attention to these deep-layer skeletal morphologic facts. They tended to focus energy on the soft-tissue details without giving enough thought to the effects of the underlying skeletal framework for facial aging. Attempts to camouflage an underlying maxillary deficiency with techniques such as excess fat grafting to fill the soft-tissue lower eyelid envelope; the removal of excess skin to "smooth out" the eyelids; excessive repositioning or tightening of the deep soft-tissue layer (i.e., the submuscular aponeurotic system) to manage descent; and excessive hard-tissue augmentation of the zygomatic prominence and the infraorbital region are all likely to result in a poorly contoured and unnatural appearing midface and periorbital region. This camouflage approach should be compared to the more favorable direct management of the anterior maxilla and the perinasal regions through orthognathic surgery.

Consideration of Craniofacial Morphologic Change with Age: Does it Occur?

Although it has been much discussed, there is little convincing evidence to suggest that the craniofacial skeletal structures either significantly atrophy or hypertrophy with age after traditional growth maturity is reached.[11,12,17,28,35-38,43,68,84,89,92,109,120,126,127,153] This should not be confused with the documented facial changes that do occur in association with the loss of teeth; occlusal surface erosion; the ongoing eruption of teeth; and disease of the periodontium. With extensive dental loss, significant deterioration of the horizontal projection, the vertical height, and transverse width of the midface and the lower face will unquestionably alter the soft-tissue drape and result in a more aged look. After skeletal maturity is reached (i.e., 14 to 16 years of age in girls and 16 to 18 years of age in boy) and in the absence of dental loss or significant deterioration, neither notable atrophy nor hypertrophy of the craniofacial prominences has been convincingly proven to occur. This specifically includes the following structures:

- The supraorbital ridges
- The lateral orbital rims
- The infraorbital rims
- The zygomatic prominences
- The nasal height and the frontonasal angle
- The pyriform rims and the anterior nasal spine
- The gonial regions of the mandible
- The pogonion prominence

Midface Skeletal Change with Age: Does it Occur?

In 1927, **Hellman** proposed the theory that the facial skeleton continues to grow throughout life[58]; he called this process *morphological differentiation.* **Pessa and colleagues** proposed an algorithm of facial aging to support Hellman's theory on the basis of the review of a limited number of radiographs that suggested to him that bony changes of the midface (i.e., the zygoma and the infraorbital rim) occurred with age.[95] The data that were used to support

this theory were collected from computed tomography scans performed on just 12 men: six with a mean age of 20 years and six with a mean age of 56 years. These scans were not obtained for the same individuals over time, and they were not selected in a controlled fashion. Pessa made four difficult-to-reproduce angular measurements in each midface region on each scan (i.e., the glabellar angle, the orbital angle, the pyriform angle, and the angle of the maxillary wall). He concluded from the limited data that "the craniofacial skeleton continues to change with age resulting in remodeling of the maxilla [clockwise rotation] relative to the cranial base."[95] Despite Pessa's theory, no scientific data confirm significant changes in the midface skeleton with age.

Levine and colleagues have also found fault with the "skeletal-aged" theories of Pessa and colleagues.[70,71] They contend that Pessa's theory of midface skeletal atrophy with age is based on an unsound interpretation of data from a limited number of non-longitudinal computed tomography scans and that it is not consistent with clinical observations or available research. Levine does believe that, in the presence of maxillary deficiency, soft-tissue descent and volume loss with age lead to the frequently observed unattractive changes seen in the midface periorbital region. He goes on to state that the negative vector relationship of the ocular globe and the lower eyelid in this subgroup of adults is more likely the result of a longstanding horizontal (sagittal) maxillary hypoplasia that has been present since the teenage years. It is the longstanding developmental midface skeletal deficiency that does not provide adequate support for the overlying soft tissues.[41] As a result, retaining ligaments eventually give way, the fat may then atrophy or protrude, and the skin becomes lax.

Whether the negative vector eyelid aging characteristics (i.e., rounding of the palpebral fissure, lengthening of the lower lid, and loss of cheek prominence) results from a developmental skeletal midface hypoplasia or from skeletal atrophy with continued aging, most informed clinicians agree that the correction of the baseline bony deficiency is a key aspect of a natural-appearing rejuvenation. **Yaremchuk's analysis** and clinical results are convincing evidence that the underlying skeleton is often where attention should be directed if effective rejuvenation is desired.[141-149] Free fat grafting, the injection of various fillers, and the redistribution of the midface and lower lid soft tissues have more limited roles in the presence of a deficient skeletal framework. Too much attention given to the soft tissues or to imprecise skeletal augmentation will predictably result in an operated look that is visually obvious for all to see.

Mandibular Skeletal Change with Age: Does it Occur?

Pessa and colleagues also hypothesized that the mandible changes in shape during the aging process after normal skeletal maturity.[98] The authors tested this theory in just 16 subjects (eight male subjects and eight female subjects) with the use of acetate tracings of frontal (posteroanterior) cephalograms taken during two different time frames. The first group ranged in age from 5 to 17 years, and the second group ranged in age from 46 to 60 years. Seven difficult-to-reproduce data points were chosen along the inferior border of the mandible on each radiograph; an analysis was carried out with the use of these points. From this data, the authors theorized that the "youthful mandible had a greater degree or curvature whereas the mature [middle-aged] mandible can be described as having a less convex curvature" and that "the mandible increases in size [length] with continued growth." A critical review of Pessa's methods suggests that the posteroanterior cephalometric radiographs of the young study subjects were not standardized for head position (i.e., flexion and extension) as compared with the radiographs taken of the older subjects. Therefore, the accuracy of the comparison measurements taken along the inferior border of the mandible on each of the non-longitudinal radiographs is questionable. This inaccuracy is caused by inherent distortions that result from differences of positioning of the subjects' heads at the time that the two-dimensional radiographs were taken.

Shaw and colleagues recently reviewed computed tomography scans of dentate Caucasian subjects; they included an equal number of women (n = 60) and men (n = 60) in an attempt to identify changes in mandibular morphology with age.[121] The patient population was not evaluated longitudinally, and it was not standardized. The radiographs were taken from a hospital-based data pool and not controlled to exclude those with jaw deformities, significant malocclusions, congenital anomalies, or trauma. The researchers further subdivided the radiographs into three groups in accordance with the age brackets of the patients (i.e., 20 to 40 years, 41 to 64 years, and >65 years). The authors took measurements from each scan related to the width and length of the mandible and at the gonial angles. Interestingly, the authors drew conclusions from these data that are contradictory to those of published studies carried out by other investigators with the similar intention of clarifying the effects of age on mandibular morphology. For example, the study by **Pecora and colleagues** suggests that the mandible continues to grow in length in both men and women during aging.[94] Pessa and colleagues also suggest that there is an increase in mandibular width, height, and length with aging. The analysis by **Bartlett and colleagues** of postmortem human skull data suggest that there is an increase in the width—but not the length—of the mandible with age.[7]

NOTE: Despite differing assertions and opinions offered by a handful of authors, in the absence of the loss of the teeth or the significant alteration of the dentition, no reproducible convincing data confirms significant changes in the shape of the mandible with aging.

Recovery in the Adult after Orthognathic Surgery

Physiologic and Psychosocial Effects

Although the middle-aged adult's basic maxillofacial skeletal and soft-tissue healing capacity is in most cases similar to that of a teenager or young adult, their return of energy level, oromotor function, sensation (i.e., the infraorbital nerve and the inferior alveolar nerve), and psychosocial readiness to resume preoperative daily activities and work-related matters may be more prolonged. For example, the teenager will typically return to schoolwork, computer work, reading, and desk-type activities by 2 weeks after his or her procedures, even after complex jaw and intranasal surgery. These patients may have concerns about the perceptions of their peers, but in general a rapid return to the presurgery environment is expected. For the middle-aged adult, returning to a competitive activity schedule at work (e.g., business telephone conversations, conferences, meeting new clients, engaging in sales-type activities) and feeling comfortable around family and friends is generally more challenging and will require extra preparation, planning, and discussion between the surgeon and the patient. Aspects of greater concern for the middle-aged adult as compared with the teenager include rehabilitation requirements and personal adjustments to the following: 1) facial region sensory loss and recovery; 2) limitations of mouth opening; 3) changes in occlusion; 4) changes in speech articulation; 5) lingering general fatigue; 6) persistent soft-tissue swelling and "tightness" during dynamic expression; and 7) altered body image.

NOTE: This author has found that an adult patient's recovery is best and his or her satisfaction is highest when he or she has an upbeat and optimistic attitude; when immediate family members and friends are available and supportive; when there is a documented need for and advantage to simultaneous improvements in: the upper airway; the occlusion and dental health; and when there are clearly defined tangible aesthetic objectives.

Setting Clear Objectives with Realistic Expectations

All parties involved should agree on the treatment objectives and accept the risks and limitations of the planned surgical procedures. Unfortunately, the patient's preoperative psychosocial assessment, the surgeon's understanding of unique wound healing requirements, and the uncertainties of surgery are not completely predictable. Furthermore, orthognathic surgery should not be carried out with a belief that it will repair broken personal relationships, save jobs, or overcome financial concerns. The reality is that a small percentage of patients will perceive an unfavorable surgical outcome even when the clinicians feel that the results are at least satisfactory. Others will not accept a complication even though the risks were explained in advance and all reasonable precautions were taken. Experience has shown that there are no shortcuts to thorough patient education; comprehensive care must be provided every step of the way (see Chapter 7).

Body Dysmorphic Disorder

To minimize patient disappointment after surgery, an informal (and, in some cases, a more rigorous) psychosocial assessment is indicated. The clinician must keep in mind that some individuals who are seeking treatment will have a true psychiatric disorder. Body dysmorphic disorder is a medical condition that can be difficult for a clinician to recognize before surgery. If this condition is present, it will be a predictable cause of unhappiness after surgery. It is estimated that 7% to 15% of individuals who are pursuing cosmetic surgery may have body dysmorphic disorder (see Chapter 7).

Sensory Loss and Incidence of Dysesthesia

Inferior Alveolar and Mental Nerve Injury and Recovery

During sagittal split ramus osteotomies of the mandible, the inferior alveolar nerve can be directly damaged by a burr on a rotary drill, a blade on a reciprocating saw, or a chisel used to complete the split. The nerve can also be compressed during osteotomy stabilization (i.e., plate and screw fixation). Studies document that, with time, inferior alveolar nerve sensory function is generally sufficient in most patients, although complete recovery is uncommon. The exact reasons why, over time, most patients experience only a degree of simple loss of sensation in the distribution of the inferior alveolar nerve, some continue to experience active sensations that are not normally present but are of little concern, and a small percentage have active sensations that are subjectively uncomfortable or painful (i.e., dysesthesia) is not known. Zuniga and colleagues (see chapter 16) report a 5% incidence of dysesthesia of the inferior alveolar nerve after sagittal split ramus osteotomy (see Chapter 16 for a more complete review of the literature).

Infraorbital Nerve Injury and Recovery

A degree of injury to the infraorbital nerve at the time of Le Fort I osteotomy that results in paresthesia is expected, whereas long-term dysesthesia of the cheek skin, the upper lip, the palatal mucosa, and the gingiva is less common. Infraorbital nerve injury may result from compression, stretching, or direct injury from saw blades, burs, or hand-held instruments. A study by Thygesen and colleagues (see Chapter 16) found continued changes (i.e., less than full recovery had occurred) in somatosensory infraorbital nerve function 12 months after Le Fort I osteotomy in 7% to 60% of patients. This included the regions of the cutaneous skin, the lip, the gingiva, and the palatal mucosa. Fortunately, the authors did not find instances of significant

dysesthesia associated with the documented sensory loss in any of the study patients (see Chapter 16 for a more complete review of the literature).

Patient Age and Sensory Recovery

It is believed that older patients (i.e., >25 years old and especially >40 years old) who sustain the same extent of injury to either the infraorbital nerve or the inferior alveolar nerve after maxillary or mandibular osteotomies, respectively, will not experience the same degree of subjective sensory recovery as younger individuals. It appears that the time required for "acceptable" subjective recovery of facial and oral sensation is longer and that the percentage of middle-aged adults who have undergone these operations and who interpret their lack of full sensory return as dysesthesia (i.e., uncomfortable sensory loss) is higher than that observed among teenagers and young adults (see Chapter 16). Adults are more likely to complain about a lack of sensory return to the mucosa of the palate and the gingiva. They may be annoyed by the lack of proprioception when flossing and when managing food on the roof of the mouth. Interestingly, Pogrel and colleagues documented that, with time, men tend to achieve a more tolerable decrease in these uncomfortable sensory symptoms than women.[102]

Conclusions

The surgical techniques for the correction of a dentofacial deformity are generally the same for the middle-aged adult as for the teenager and the young adult. To achieve a favorable result in the adult orthognathic patient, it is essential to recognize age-related treatment pitfalls such as medical risk factors; progressive upper airway obstruction; dental rehabilitation needs, including periodontal and restorative aspects; effects of facial soft-tissue aging; and the often prolonged physiologic and psychosocial response to surgery. An important observation is that, in the presence of a baseline jaw disharmony, the overlying soft-tissue envelope will tend to show premature and unattractive aging. Adults who undergo successful orthognathic surgery are likely to experience a quantum change when they look younger and more attractive than they did earlier during their lives.

- Conclusions

Researchers are increasingly finding that a lack of sleep is detrimental for our health. Sleepiness has been linked to increased rates of heart disease, obesity, stroke, and even certain cancers. The exact reasons for these effects are still largely unknown, but they give support to the theory that sleep is the time when our bodies naturally repair themselves on a cellular level.[150] Sleep—or the lack of it—is now thought to be a complex process that underpins everything from the ability to learn a new skill to how likely we are to find a novel solution to a problem.[243] It is also considered a vital part of happiness and one of the best forms of preventative medicine.[288]

Sleep disorders include conditions that are characterized by repeated pauses in breathing during sleep, which lead to the fragmentation of sleep and decreases in oxyhemoglobin saturation. The physiologic spectrum of sleep-disordered breathing ranges from partial airway collapse with increased upper airway resistance, which is manifested as loud snoring and episodes of hypopnea, to complete airway collapse and prolonged episodes of apnea. Obstructive sleep apnea (OSA) is clinically defined by frequent episodes of apnea and hypopnea as well as symptoms of functional impairment.[13,14,129,130]

According to the National Sleep Foundation, some form of snoring or OSA occurs in 90 million Americans.[245,246] Approximately 40% of individuals who are more than 40 years old snore, and half of them snore every night. Among habitually loud snorers, the incidence of OSA is at least 17% in men and 15% in women. The Foundation estimates that 16 million of the 20 million Americans with OSA remain undiagnosed. Affected individuals are often aware of snoring, daytime sleepiness, poor sleep patterns, and complaints from bed partners.[352] To the educated clinician, the diagnosis of OSA may seem clear, but the affected individuals and their families are often unaware.[9,106]

Young and colleagues carried out a study to determine the prevalence of sleep-disordered breathing.[393-395] With the use of a random sample of 602 employed men and women who were between the ages of 30 to 60 years old and who were studied via overnight polysomnography (PSG), these authors assessed the frequency of episodes of apnea and hypopnea per hour of sleep. The authors determined that this condition affected up to 9% of middle-aged women and 24% of middle-aged men (i.e., an apnea–hypopnea index [AHI] of 5 or more and daytime hypersomnolence).[185] Both male and female habitual snorers tended to have a higher AHI of 15 or more.

Although obesity is often given as the cause of OSA, evidence supports the idea that a significant percentage of individuals with OSA have an anatomic predisposition to airway collapse (i.e., retrusive jaws and obstructed nasal cavities). Clinical studies confirm that maxillary–mandibular–chin advancement (MMCA), which is often combined with intranasal procedures (i.e., septoplasty, inferior turbinate reduction, and nasal floor recontouring), is relatively safe and highly effective for the treatment of OSA when multiple sites of upper airway narrowing are present. Published studies consistently document that MMCA is the most effective surgical alternative to tracheostomy, with results that are comparable to the therapeutic efficacy of nasal continuous positive airway pressure (CPAP). This chapter will review several aspects of OSA, including its diagnosis, the characterization of its severity and the rationales for its various treatment options.

Rationale for Treatment

The two major rationales for the treatment of OSA are to address 1) pathophysiologic derangements and 2) behavioral derangements.[263]

The *pathophysiologic derangements* related to OSA are primarily cardiorespiratory in nature.* They include increased risks of myocardial infarction, stroke, and sudden death.[153] Sudden death may be caused by tachycardia and tachyarrhythmias (i.e., atrial fibrillation) as well as by bradyarrhythmias. The documented high prevalence of atherosclerotic coronary artery disease among patients with OSA is possibly related to endothelial damage, with platelet activation and the presence of inflammatory mediators also being involved.[153] When OSA is combined with systemic hypertension, an increased incidence of stroke has been reported.[138,140,392] A higher-than-average occurrence of idiopathic dilated cardiomyopathy and more frequent episodes of ST-segment depression have also been recognized.[118,125,153] The physiologic processes that are believed to be involved in OSA and that predispose patients to these risks include hypoxemia, negative intrathoracic pressure, and the disequilibrium of the autonomic nervous system.[42]

The *behavioral derangements* caused by OSA may be the result of excessive daytime sleepiness.[161,367] OSA is associated with nocturnal arousals during sleep that occur in response to airway collapse and that result in poor sleep. Excessive daytime sleepiness manifests as sleepiness or fatigue of such a degree that the individual lacks vigilance and does not function as well as he or she should during the day. Other symptoms typically include heavy snoring, known apnea, headaches, difficulty waking in the morning, fatigue, sleepiness after eating, memory loss, having difficultly with work interactions, stressed relationships and sexual performance complaints. There is a documented increased incidence of motor vehicle accidents and job-related injuries among individuals with OSA (e.g., individuals with OSA are 10 times more likely to die in an automobile accident).[26,85,103,292] OSA is also known to be a cause of difficulty with concentration at school or during work activities. Over time, the hypoxia that is caused by OSA is believed to result in changes in the neurons of the hippocampus and the right frontal cortex of the brain. Neuroimaging studies have revealed evidence of hippocampal atrophy in people who chronically suffer from OSA. Clinically, it is documented that a greater percentage of patients with OSA have problems with mentally manipulating nonverbal information and with executive processing.[100] Interestingly, there is not a direct correlation between these behavioral derangements and the severity of OSA as measured with the AHI or with specific levels of oxygen desaturation. It is important to note that there are multiple causes of excessive daytime sleepiness other than OSA, including volitional sleep deprivation, alcoholism, insomnia, and narcolepsy.

Diagnosis, Characterization, and Assessment of Obstructive Sleep Apnea Severity

Pathophysiology

OSA is characterized by symptoms that result from the recurrent sleep-associated collapse of the pharyngeal airway and that lead to hypoxemia, hypercapnia, and fluctuations in intrathoracic pressure caused by increased respiratory effort, with arousal from sleep required to reestablish airway patency. When awake, protective mechanisms increase the activity of the pharyngeal dilator muscles; however, during sleep, these mechanisms may fail and result in the collapse of the pharyngeal airway.[45,73,120,293,329,346,349,387] This is made worse by nighttime horizontal and supine sleep positioning.[244,256] Frequent locations of pharyngeal collapse include the velopharynx (behind the soft palate), the oropharynx (behind the tongue), or both.[240]

Schwab and colleagues have documented an increase in adipose hypertrophy within the floor of the mouth, the soft palate, the pharyngeal fat pads, and the lateral pharyngeal walls in many individuals with OSA.[324] In patients with obesity, there is a direct deposition of fat that causes submucosal adipose volume expansion within the pharyngeal walls (thus narrowing the lumen) and the floor of the mouth (thus causing elevation and retro positioning of the tongue), thereby diminishing the actual upper airway breathing space and, in many cases, explaining the greater extraluminal critical closing pressure documented in patients with OSA. Evidence supports the concept that many individuals with OSA have an anatomic predisposition to airway collapse as a result of retrusive jaws and obstructed nasal cavities. An individual's unique baseline skeletal (i.e., jaw) anatomy may have a dramatic effect on the size (i.e., the luminal diameter) of the upper airway. It is now also appreciated that the variability in upper airway breathing space from one person to the next is influenced by the subject's developmental or congenital maxillofacial skeletal morphology. Deficient maxillomandibular structural support adds to the environmental causes (i.e., weight gain) that thicken the pharyngeal soft tissues, thereby further narrowing the lumen and diminishing the patency afforded by pharyngeal dilator muscle contraction forces that work to maintain and open the airway. Genetics plays a lesser role in the observed volumes of the tongue, the soft palate, the adenoids, the turbinates, and the tonsillar tissues seen in individuals with OSA. These soft-tissue structures are more likely to be affected by acquired conditions such as weight gain, infections, or allergies. With obesity, there may also be alterations of pharyngeal muscle orientation and function. These factors combine to determine overall upper airway breathing space, pharyngeal muscle function, and, as a consequence, the occurrence of apnea events during sleep.

Schwartz and colleagues measured the critical closing pressures during sleep in individuals with OSA and

compared these values to those of controls (i.e., individuals without OSA).[327] Individuals with baseline anatomically "large-volume" airways are less dependent on pharyngeal dilator muscles to maintain airway patency than those with intrinsic "small-volume" anatomic airways. Schwartz and colleagues showed that control subjects (i.e., individuals without OSA) typically have critical closing airway values of less than 0 cm of water, whereas those with severe OSA have values of more than 8 cm of water. Multiple diagnostic modalities (e.g., cephalometric x-rays, computed tomography [CT] scans, acoustic reflection, magnetic resonance imaging) confirm that individuals with OSA generally have "smaller-volume" baseline awake airway lumens as compared with controls.[264]

According to Fogel and colleagues the pharyngeal muscles of primary importance fall into three groups[87]:

1. The muscles that influence the hyoid bone position (i.e., geniohyoid, sternohyoid)
2. The muscles of the tongue (i.e., genioglossus)
3. The muscles of the soft palate (i.e., tensor palatine and levator palatine)

The activity of these muscles is normally increased during inspiration to stiffen and expand (i.e., open) the upper airway. This counteracts the collapsing influences that would otherwise occur with inspiratory negative airway pressure. During expiration, the muscles normally substantially relax while positive pressure is flowing through the respiratory tree. The tensor palatine is an exception in that it must maintain a constant level of tone throughout the respiratory cycle to preserve a patent airway. Fogel and colleagues stated that the activity of the pharyngeal dilator muscles during wakefulness is tightly controlled to maintain pharyngeal patency.[87] In individuals with an anatomically "small-volume" airway, the activation of this negative-pressure reflex (i.e., feedback mechanism) to increase the function of the pharyngeal muscles must occur to prevent or limit apnea. This reflex has been shown to be diminished in apnea-prone individuals for both the genioglossus and the tensor palatine muscles. An individual's use of specific medications (e.g., alcohol, sedatives, narcotics) will also negatively influence the reflex arc, thereby causing the relaxation of the muscles and further diminishing airway patency.

At least until the age of 65 years, age is positively correlated with OSA severity as demonstrated by an increase in the AHI.[152] This increase is substantially greater in the presence of baseline maxillomandibular sagittal deficiency. While a person is awake, neuromuscular mechanisms and body position (i.e., standing or sitting up) can positively influence and compensate for the "small-volume" airway. However, the pharyngeal dilator muscles are less able to effectively contract during sleep, which results in the more frequent collapse of the anatomically small breathing space. The ability of the pharyngeal muscles to compensate for and prevent apnea events becomes progressively more difficult with age and in the presence of weight gain.

Frieberg and colleagues hypothesized that a progressive lesion in the afferent and/or efferent nerve pathways caused by repetitive "snoring trauma" may also contribute to the collapsibility and obstruction of the upper airway that is seen in patients with OSA.[89-91] Their study evaluated the hypothesis of the presence of a progressive neurogenic lesion in the pharyngeal muscles in patients with longstanding upper airway obstruction. Biopsies of palatopharyngeal muscle were obtained from patients (n = 21) with habitual snoring and degrees of upper airway obstruction and compared with those of non-snoring control subjects (n = 10). The degree of abnormality found was significantly increased in the study patients as compared with control subjects. The results of their research support the hypothesis of a progressive local neurogenic lesion that is caused by the "trauma of snoring" as a possible contributory factor in upper airway collapsibility.

Sleep electroencephalograms (EEGs) of patients with OSA will differ from those of individuals with upper airway resistance syndrome (UARS) and from those of control subjects.[117,128] The arousal response of individuals with OSA is delayed, despite the fact that increased respiratory effort is seen during the obstructive phase. This delayed arousal response has been confirmed by differences in the patterns of EEG findings. Guilleminault and colleagues hypothesized that a difference in sensory input may be the responsible factor for the divergent responses to the abnormal breathing patterns that may exist between individuals with UARS and those with OSA.[122] The authors set out to compare the results of a palatal mucosa two-point discrimination response in normal subjects (n = 15), those with OSA (n = 15), and those with UARS (n = 15). The subjects were matched for age, sex, and body mass index. The 45 subjects were submitted to a two-point discrimination study of the palatal mucosa during wakefulness. Individuals with OSA had a clear impairment of their palatal mucosa sensory input with a significant decrement in two-point discrimination. Interestingly, the subjects with UARS and the normal control subjects responded similarly to each other. The responses seen in individuals with UARS indicate that those individuals are more capable of transmitting sensory inputs than individuals with OSA. This may be at least one factor that explains the difference in arousal response that is been documented in patients with UARS as compared with those with OSA.[122]

For the individual with OSA, as apnea events become more frequent, hypoxemic and hypercarbic episodes require increased respiratory effort to ultimately achieve arousal from sleep. With awakening from the apnea event, there is a reestablishment of airway patency, and ventilation proceeds. The individual then returns to sleep, and the cycle repeats itself. This repetitive pattern of sleep disruption not only affects the quality of the individual's life (i.e., behavior derangements), but it also affects their longevity (i.e., pathophysiologic derangements).

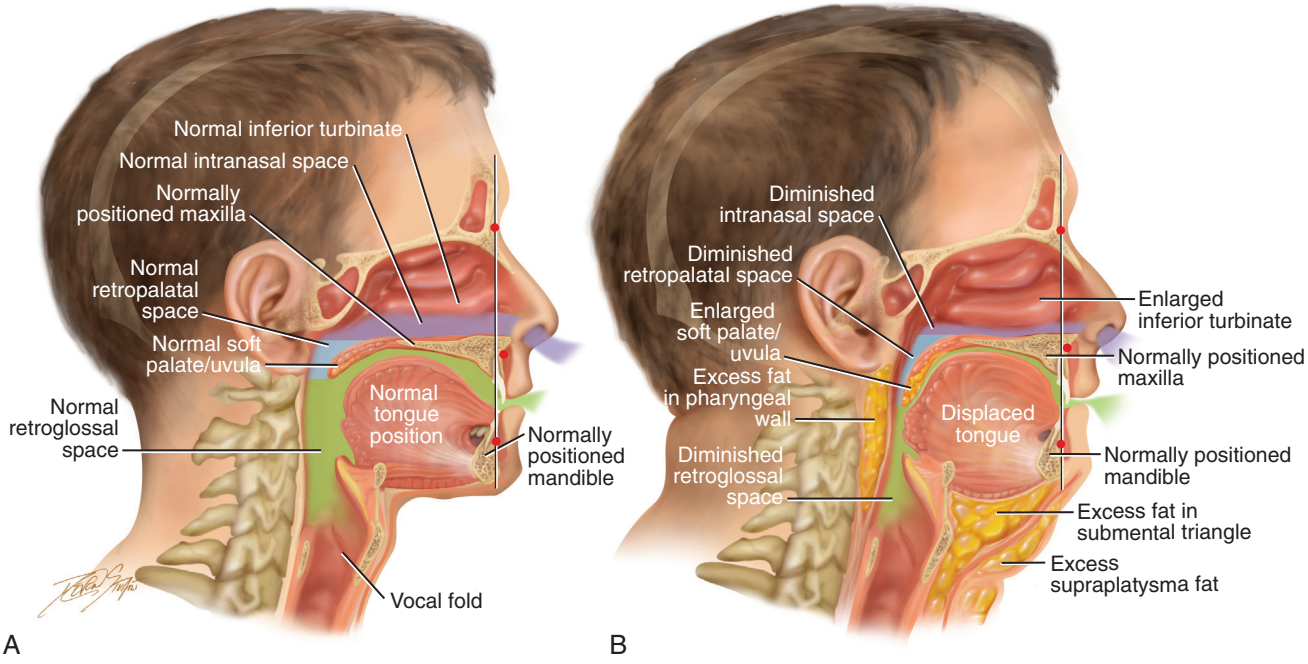
The basic anatomic factors that reduce the size of the upper airway include the following:

1. Regional obesity (i.e., increased volume of the lateral pharyngeal fat pads, the soft palate, and the floor of the mouth
2. Baseline (inherent) abnormalities of the maxillomandibular skeletal structures (i.e., the maxilla, the mandible, and the nasal septum)
3. Volumetric enlargement of upper airway soft-tissue visceral structures (e.g., tongue, soft palate, tonsils, adenoids, inferior turbinates) as a result of congenital anomalies, allergies, infections, or tumors.

The term *pharynx* is used to describe the anatomic region that extends from the esophageal entrance up to the back of the nose. It is further subdivided according to proximity to the nose, mouth, and throat down to the larynx. Together, these pharyngeal structures are involved in critical physiologic functions, including breathing, swallowing, vocalization/speech, and mastication. Each of these functions is potentially influenced by any one of the upper airway anatomic components. The upper airway functions as a continuous cohesive organ; it is commonly defined as the soft-tissue region that is bounded by the nasopharynx superiorly, the epiglottis inferiorly, the maxillomandibular complex anteriorly, and the spinal column posteriorly. The upper airway is somewhat artificially subdivided into the following regions:

1. *The intranasal region.* This portion of the airway extends from and includes the external nasal valves, the internal nasal valves, the turbinates, the nasal septum, and the adenoids.
2. *The retropalatal region.* This portion of the airway is primarily affected by the position of the maxilla (i.e., the hard palate), the size and position of the soft palate, the tonsils, and the parapharyngeal fat pads.
3. *The retroglossal region.* This portion of the airway is primarily affected by the position of the mandible, the size and position of the tongue, the fullness of the soft tissues in the floor of the mouth, the parapharyngeal fat pads, and the tonsils.

An increased body mass index (BMI), which is also known as *obesity,* is a known risk factor for OSA in children, adolescents, and adults (Fig. 26-1).[21,88,241,255,337] Peppard and



• **Figure 26-1** **A,** Midline sagittal cross-section head and neck illustration of a 20-year-old man with a normal body mass index to demonstrate upper airway space and associated maxillofacial anatomy. This individual has a normal upper facial skeleton (cranial vault, orbits, and zygomas), a normal lower facial skeleton (maxilla and mandible), and normal soft tissues (soft palate, tongue, tonsils, and adenoids). The intranasal cavity, which includes the turbinates and the septum, is also normal. **B,** The same individual when he is 50 years old with an elevated body mass index. The upper and lower facial skeleton remain unchanged with age. The adipose cells, which are scattered throughout and within the upper airway soft tissues, have now increased in volume. This includes the retropharyngeal and the lateral pharyngeal tissues, the soft palate, and the floor of the mouth. As a result, the soft palate is long, thick, and in close proximity to the posterior and lateral pharyngeal walls, thereby diminishing the retropalatal space. As a result of increased adipose volume in the floor of the mouth, the tongue has been displaced superiorly and posteriorly, thus decreasing the retroglossal airway space. As a result of chronic allergies, the patient's turbinates have enlarged to cause increased nasal airway resistance (i.e., diminished intranasal airway space). There is also excess adipose volume in both the submental triangle and the supraplatysmal locations, thereby resulting in a full neck and a "double chin" appearance. In review, when the patient was 20 years old, he had normal upper airway space, including the intranasal site; the retropalatal site; and the retroglossal sites. When he was 50 years old, the upper airway space is considerably smaller, including the intranasal space, the retropalatal space, and the retroglossal space. The patient depicted here now has documented obstructive sleep apnea.

colleagues outlined the cardiovascular risks associated with OSA for weight gain and weight loss.[269,268] Excessive body weight was found to be positively associated with OSA,[262] and the stability of the individual's weight was also found to be an important factor. A 10% weight gain predicted a 32% increase in the AHI.[319] The same 10% gain in weight also predicted a six-fold increase in the odds of moderate to severe OSA developing. Interestingly, a weight loss of 10% predicted a 26% decrease in the AHI.[169] Unfortunately, studies consistently document that weight loss programs in patients with OSA frequently fail miserably. Any weight loss that the individual is able to initially achieve tends to be temporary.[167]

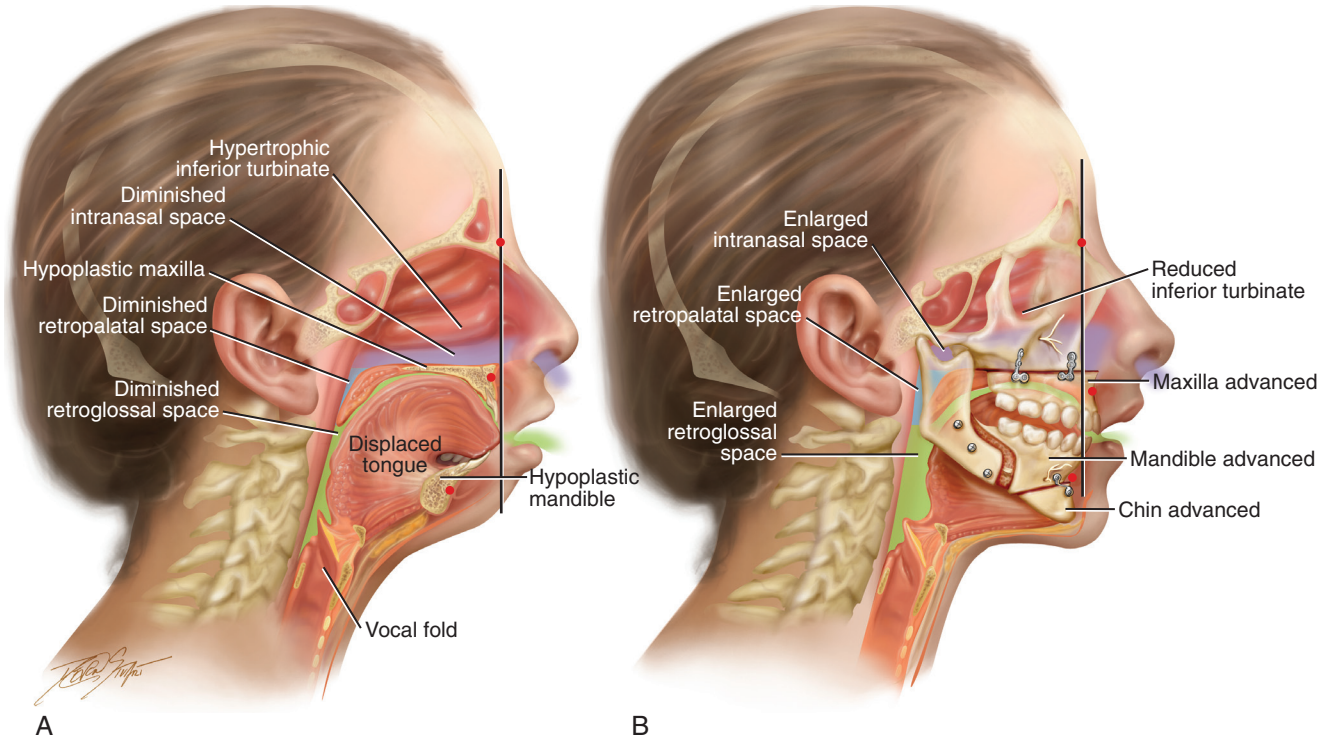
When an individual's BMI is elevated, the volume of fat in the pharynx and the floor of the mouth also increases. It is estimated that more than 66% of individuals with OSA are obese. On the basis of the latest World Health Organization statistics, it is estimated that there are more than 1.6 billion overweight adults (from a total population of 6.5 billion) and at least 400 million obese individuals (BMI ≥ 25 kg/m^2) on Earth.[72] Obesity has both a genetic and an environmental basis.[37,63,102,165,237] A review of population studies suggests that heredity accounts for at least 40% of the variance in BMI.[219,286] Studies have demonstrated a strong relationship between the BMIs of biologic parents and their children. Interestingly, no relationship between the BMI of adoptive parents and their adopted children has been documented. The best indirect indicator of excessive fat accumulation in the pharyngeal region and the floor of the mouth is a person's BMI.

Studies have also documented that relatives of individuals with OSA demonstrate a higher incidence of hypoplastic maxillae and mandibles, longer soft palates, and wider uvulas as compared with matched controls.[219,326] This also speaks to the hereditary component of a small pharyngeal airway space and to an individual's genetic predisposition to OSA.[295,388]

There are specific syndromes and conditions that result in severe maxillomandibular skeleton dysmorphology and that also negatively affect the upper airway (e.g., Crouzon syndrome, Apert syndrome, Treacher Collins syndrome, Pierre Robin sequence).[17,38,270,271,287,341,354,390] It is documented that more than 50% of individuals with Down syndrome suffer from OSA.[66] Interestingly, a similar percentage of individuals with Down syndrome are known to have a baseline intrinsic developmental jaw deformity that is characterized primarily by maxillary deficiency. The surgical correction of the maxillofacial deformities associated with these syndromes have been documented to enlarge the upper airway space and to improve and often resolve breathing difficulties, including OSA (see Chapters 27, 28, 30 and 31). The surgical management of velopharyngeal insufficiency (i.e., superiorly based pharyngeal flap or sphincteroplasty) in individuals with a repaired cleft palate is also known to result in OSA in some cases.[4,39,157,176,187,205,257,258,339,340,343,373,389,396] Interestingly, the non-syndromal developmental dentofacial deformities (e.g., long face growth pattern, short face growth pattern, primary mandibular deficiency, maxillary deficiency with relative mandibular excess, maxillary hypoplasia associated with repaired cleft palate), which affect at least 5% of the general population, also negatively affect the upper airway.[212] Unfortunately, these more common patterns of jaw disharmony frequently go unrecognized as significant etiologic factors for OSA (Figs. 26-2 and 26-3). It is incumbent on the otolaryngologist, the pulmonologist or sleep specialist, the pediatrician or internist, the orthognathic or maxillofacial surgeon, and the general dentist or orthodontist to understand the fundamental relationship between developmental jaw deformities and upper airway obstruction in each patient who is evaluated.

Not infrequently, the individual with "mandibular prognathism" has undergone a lower jaw set-back treatment to improve the occlusion. Historically, such procedures have been preferred by many clinicians for the treatment of skeletal Class III patterns. However, it is now known that this approach is associated with a risk to the airway size and shape.[6,18,41,48,67,68,74,78,84,113,115,171,172,174,314,316,370,386] Demetriades and colleagues confirmed the clinical importance of considering the airway when formulating a treatment plan for the correction of so called "mandibular prognathism."[69] They described 26 patients who presented with developmental dentofacial deformities that were characterized by maxillary deficiencies in combination with relative mandibular excesses. Each patient underwent mandibular ramus osteotomies with at least some set-back. The patients were divided into two groups. The Group 1 patients (n = 13) underwent mandibular setback of at least 5 mm without simultaneous Le Fort I osteotomies. The Group 2 patients (n = 13) also underwent a degree of mandibular set-back, but in conjunction with Le Fort I advancement. All study patients (Groups 1 and 2) underwent preoperative and postoperative lateral cephalometric radiography and portable PSG. The preoperative and postoperative radiographs were compared, and any changes that occurred in the position of the hyoid bone, the distance from the posterior nasal spine to the palate, the retrolingual space, and the hypopharyngeal space were measured. The authors confirmed that mandibular retropositioning of at least 5 mm can significantly decrease the posterior airway space and cause mild to moderate OSA. The study also suggested that, when a limited mandibular set-back is carried out in combination with maxillary Le Fort I advancement, significant negative effects on the airway are likely to be prevented.

In summary, anatomic upper airway risk factors for OSA include the following: 1) regional obesity (i.e., increased upper airway submucosal adipose tissue deposition); 2) retrusive maxillomandibular skeleton (e.g., hypoplasia of the maxilla or mandible); 3) alterations in the intranasal cavity (e.g., septal deviations, hypertrophic inferior turbinates, tight nasal aperture, elevated nasal floor, adenoid hypertrophy); 4) enlargement of other critical upper-airway soft-tissue visceral structures (e.g., soft palate, tonsils,



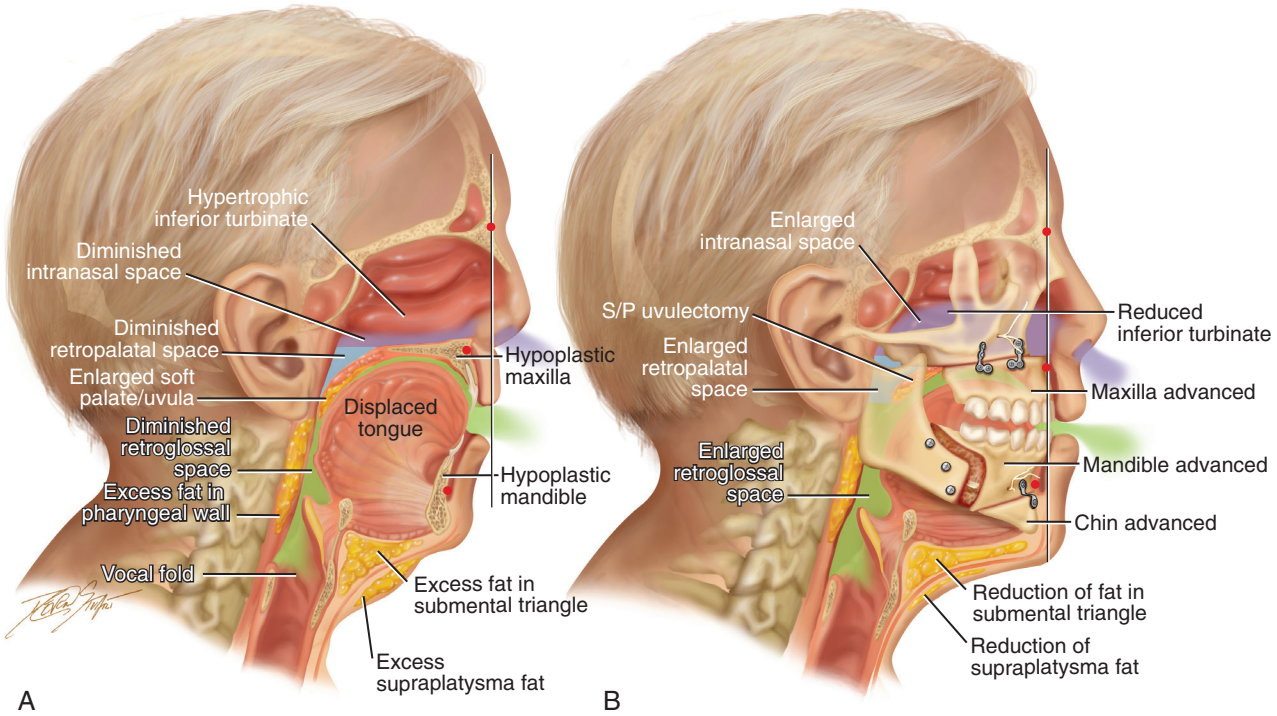
• **Figure 26-2** Midline sagittal cross-sectional head and neck illustrations of a 16-year-old girl with primary mandibular deficiency, maxillary arch constriction, and Class II excess overjet malocclusion (see Fig. 19-4). The illustrations demonstrate the upper airway space and the associated maxillofacial anatomy before and after jaw and intranasal reconstruction. **A,** Illustration when the patient was 16 years old, before intervention. The inferior turbinates are hypertrophic as a result of chronic allergies, and the nasal septum is deviated. These findings result in a diminished intranasal airway space. As part of the developmental jaw deformity, the maxilla is retropositioned, and there is a narrow arch width. Therefore, the soft palate is posterior, which results in diminished retropalatal space. The mandible is horizontally (sagittally) deficient, with a posterior displaced tongue. As a result, there is diminished retroglossal space. The tonsils, the adenoids, the tongue, and the soft palate are displaced but otherwise normal. Although the patient is young and has a normal body mass index, the intranasal and jaw deformities result in diminished upper airway space. The patient has difficulty breathing through the nose while she is awake, and is with heavy snoring at night. Obstructive sleep apnea has been documented. **B,** The patient agreed to a comprehensive orthodontic and surgical approach. Lower bicuspid extractions allowed for the relief of dental compensation. The patient's surgery included maxillary Le Fort I osteotomy in segments (arch expansion and horizontal advancement); bilateral sagittal split ramus osteotomies (horizontal advancement); osseous genioplasty (horizontal advancement); and septoplasty and inferior turbinate reduction. The postoperative illustration indicates maxillofacial changes that resulted from the reconstruction. Now there is an expanded intranasal, retropalatal, and retroglossal airway space. There is improved nasal breathing during the day and reduced snoring and apnea events at night.

tongue); and 5) inadequate pharyngeal muscular tone (i.e., hereditary and environmental factors).[320,332,348,378] Each of these head and neck structural aspects predispose individuals to OSA by causing upper-airway narrowing during wakefulness and airway collapse during sleep. When these aspects occur in combination, the risk is greatly exacerbated. There are also specific medical conditions (e.g., myasthenia gravis, Parkinson disease, amyotrophic lateral sclerosis) as well as certain medications and drugs (e.g. alcohol, narcotics, sedatives, muscle relaxants) that are known to negatively affect the neuromotor tone of the chest wall and the pharyngeal musculature and thus predispose an individual to apnea.

Basic Clinical Evaluation

A thorough medical and sleep history should be taken and a physical examination completed. The following information should be especially considered for an individual with known OSA:

1. The clinician should determine at what specific maxillofacial skeletal locations (e.g., nasal septum, turbinates, maxilla, mandible), if any, there are negative effects occurring in the upper airway during sleep or while awake.
2. If the patient also has a high BMI (i.e., >25 kg/m^2), the clinician should determine at what regional soft-tissue locations (e.g., nasopharyngeal, palatopharyngeal, glossopharyngeal), if any, there is excessive submucosal adipose and other soft-tissue volume that may have a negative impact on the airway.
3. The clinician should determine if there are baseline physiologic dysfunctions of the lungs and chest walls (e.g., chronic obstructive pulmonary disease) that negatively affect the airway.



• **Figure 26-3** Midline sagittal cross-sectional head and neck illustrations of a 59-year-old man to demonstrate upper airway space and associated maxillofacial anatomy before and after jaw, intranasal, and facial surgery carried out primarily to open the airway (see Fig. 26-6). This patient has documented severe obstructive sleep apnea, including a respiratory disturbance index of 51 events/hour with desaturations reaching as low as 82%. The patient has an elevated body mass index and a short face growth pattern that is characterized by maxillomandibular vertical and horizontal deficiency. At the time of presentation to this surgeon, he had already undergone "Phase I" procedures including uvulopalatopharyngoplasty, septoplasty, and inferior turbinate reduction without relief of obstructive sleep apnea. **A,** Illustration of the patient's condition before surgery demonstrates hypertrophic inferior turbinates and septal deviation that result in a diminished intranasal space. The maxilla is vertically short and horizontally deficient. The soft palate is long and thick as a result of excess fat accumulation. For all of these reasons, a diminished retropalatal airway space is present. The mandible is horizontally deficient, and the tongue is elevated as a result of excess fat in the floor of the mouth. The lateral and retropharyngeal walls also show excess fat accumulation. These findings account for the diminished retroglossal airway space. **B,** After the patient was referred to this surgeon, he underwent simultaneous procedures that included maxillary Le Fort I osteotomy (horizontal advancement of 10 mm and vertical lengthening of 5 mm) with interpositional graft; bilateral sagittal split osteotomies of the mandible (horizontal advancement of 12 mm); osseous genioplasty (horizontal advancement); redo septoplasty; and anterior neck soft-tissue procedures (cervical flap elevation, fat removal, and platysma muscle plication). The illustration after maxillary–mandibular–chin advancement demonstrates the enlarged upper airway space, including the intranasal space, the retropalatal space, and the retroglossal space. A 3-month postoperative attended polysomnogram confirms a respiratory disturbance index of less than 5 events/hour.

4. The clinician should consider the effects of baseline neuromotor disorders (e.g., Parkinson disease) and currently used medications (including nonprescription drugs and alcohol) that may negatively affect the airway.

It is also recommended that a subjective questionnaire be used to assess for OSA. The Epworth Sleepiness Scale (ESS) is considered the reference standard.[86,163,164] The survey assesses the respondent's propensity for sleep in eight different situations. Although the survey is not perfect, it does provide useful information about the patient's waking sleepiness.

An airway analysis that is based on CT scan data may also be a useful tool to assess upper airway space. A recent study used three-dimensional computer analysis from cone-beam CT to present normative upper airway size reference data. The collected data confirm that, in humans, the airway size and length increases until the age of 20 years, at which time there is a variable period of stability. After this stable period, the airway at first decreases slowly in size; then, after the age of 50 years, it decreases more rapidly.[322] Li and colleagues demonstrated a correlation between the airway area and the likelihood of OSA.[197] There is a high probability of severe OSA with an airway area of less than 52 mm^2; an intermediate probability if the airway is between 52 mm^2 and 110 mm^2; and a low probability if the airway area is more than 110 mm^2.[190] Cillo and colleagues attempted to correlate specific cephalometric measurements with the AHI in a consecutive series of patients (N = 101) who were documented to have OSA. Unfortunately, no one skeletal or soft-tissue parameter could be linked to OSA.[51] Three-dimensional CT airway analysis has documented quantifiable changes in patients' oropharynges after specific surgical

interventions. This type of imaging may also be used to evaluate changes in the airway after specific medical interventions (e.g., weight loss).[75]

Susarla and colleagues used a case–control study that was designed to analyze the value of the cephalometric upper airway length (UAL) measurement as an indirect predictor of the presence and severity of OSA.[360,361] The study group included adults (n = 96) with PSG-documented severe OSA and a control group of adults (n = 56) with skeletal Class II malocclusion without known OSA. Although significant attention has been devoted to describing and measuring upper airway width, little attention has been devoted to measuring UAL. The theory behind this study is that an important component of the airway resistance is the airway length (i.e., the vertical dimension), which is known to be directly correlated with airway resistance per Poiseuille's law: resistance equals $8\ \eta L/\pi r_4$ (L = length). The results of the study suggest that the UAL (i.e., the distance between the posterior hard palate and the most superior aspect of the hyoid bone on a line parallel to the long access of the airway) is predictive of the presence of OSA in both men and women. The study results indicate that a cephalometric UAL of 72 mm or more in men and 62 mm in women was diagnostic for OSA with high sensitivity and specificity. It would appear that both a narrow posterior airway space and a long UAL predispose individuals to upper airway obstruction and that both conditions are associated with increased odds of OSA.

A reasonable predictor of OSA is a clinical triad of symptoms that includes loud snoring, apnea witnessed by a bed partner, and excessive daytime sleepiness. When the sleep and daytime history is combined with attended PSG, the patient's clinical head and neck examination (including instrumentation), and a focused radiographic analysis, then an overall picture of the upper airway anatomy and function can be seen.*

Attended Polysomnography

Overnight PSG conducted in a sleep laboratory remains the reference standard for the diagnosis of central sleep apnea or OSA.[92,111,155,180,365] PSG requires the use of several monitoring parameters, including EEG, electrooculography, electromyography, electrocardiography, the microphone measurement of snoring, pulse oximetry, respiratory inductance plethysmography, airflow measurement, and the recording of the body position. PSG primarily evaluates sleep-disordered breathing, sleep architecture, and oxygen desaturations. During PSG, episodes of apnea and hypopnea are determined from a reduction in airflow in combination with oxygen desaturation during a 4- to 8-hour time frame.

*References 1, 7, 19, 20, 22, 28, 33, 61, 64, 70, 101, 135-137, 146, 151, 156, 168, 190, 206, 210-212, 260, 281, 309, 315, 323, 338, 359, 362, 364

It is recommended that all sleep studies for a surgical patient be attended overnight PSG. Parameters reviewed after attended PSG should include the following:

- Sleep stages (both rapid eye movement and non–rapid eye movement sleep), including the percentage of sleep in each.
- Apnea index (AI)
- Hypopnea index
- Awake oxygen saturation, including the lowest levels and the stratifications of the percentage of time below specific percentiles (i.e., 90%, 80%, and 70%)
- Heart rate fluctuations (e.g., brachyarrhythmia, tachyarrhythmia)
- Periodic leg movements

To be most accurate as a diagnostic tool, the PSG study should be current (i.e., within the previous 6 to 12 months) and, if possible, not a split-night study. Split-night studies apply CPAP for the second half of the night and may underestimate the severity of OSA. An alternative to an attended sleep study is a home sleep study. Home sleep studies lack all of the monitoring parameters of an attended overnight PSG. However, advantages of home sleep studies include reduced costs and the ability to perform the sleep study in the patient's native sleeping environment. Disadvantages include the gathering of fewer sleep parameters and possibly reduced reliability.

Assessment of Apnea Severity

By convention, the severity of OSA is classically determined by the AHI. The term *obstructive apnea* refers to apnea despite continued respiratory effort. *Apnea* is defined as the cessation of airflow for at least 10 seconds in an adult or for the equivalent of two breaths in a child. *Hypopnea* is defined as 1) a substantial reduction in airflow (i.e., >50%); or 2) a moderate reduction in airflow (i.e., <50%) with oxygen desaturation of more than 3%; or 3) EEG evidence of arousal in combination with oxygen desaturation that lasts for at least 10 seconds in an adult or for the equivalent of two breaths in a child. The AHI is a count of the number of apneas and hypopneas per hour of sleep. The respiratory disturbance index (RDI) is also used to describe OSA. The RDI considers the number of apneas, hypopneas, and respiratory-effort–related arousals per hour of sleep. Respiratory-effort–related arousals are EEG arousals that are not associated with clear-cut apnea or hypopnea but rather with slight changes in airflow or respiratory effort.

In adults, an AHI of 5 to 15 is regarded as mild OSA, an AHI of 15 to 30 is considered moderate OSA, and an AHI of 30 or more is severe OSA. (OSA during childhood is discussed later in this chapter.) Interestingly, the reliability of data procured during the sleep study and its interpretation by sleep specialists has not been verified through intra-observational or inter-observational studies.

Characterization of Apnea

Central sleep apnea is characterized by a lack of drive to breathe during sleep that results in insufficient or absent ventilation with compromised gas exchange. This may occur as a result of a number of known neuromuscular disorders, or it may not have a specific cause. OSA occurs when ongoing respiratory efforts are observed during the cessation of airflow within the upper airway. Central sleep apnea, like OSA, is associated with frequent nighttime awakening; excessive daytime sleepiness; and an increased risk of adverse cardiovascular outcomes. Central sleep apnea as classically defined is relatively uncommon (i.e., it is seen in <5% of patients referred to a sleep clinic).

Interestingly, it is recognized that 10% to 20% of individuals with known OSA will fail to respond to successful anatomic surgical expansion of the maxillomandibular complex. Another difficult to explain subgroup of individuals with documented OSA is that group with apparent normal upper airway morphology (i.e., no significant narrowing). Complex sleep apnea is a newly recognized category in the spectrum of sleep apnea syndromes that helps to explain these outliers. According to Susarla and colleagues, complex sleep apnea often presents with morphologic features that are typical of obstructive disease but that are combined with PSG evidence of strongly chemoreflex-modulated sleep breathing.[360] Complex sleep apnea is distinguished from other forms of OSA by the following:

- Non–rapid eye movement sleep dominance of obstructive disease;
- Oscillations of respiration with or without flow limitation; and
- Induction of central apneas or periodic breathing with the application of positive airway pressure therapy.

Susarla and colleagues believe that a lack of resolution of OSA after successful maxillomandibular advancement surgery may occur if a ventilation control disturbance either remains or is amplified.[360] These individuals with chemoreflex-sensitive apnea can be identified, because they are extremely prone to changes in their carbon dioxide levels. It is important to make an accurate diagnosis, because these patients can be expected to require further management of the central component to their apnea. Helpful treatment for this unique subgroup may include the use of nasal oxygen, pharmacologic agents, or positive-pressure–based adaptive ventilation. Affected individuals require continued reassessment and management by a knowledgeable clinical sleep specialist.

Sites of Functional Obstruction

Studies that attempt to localize the site of upper airway obstruction in an individual with moderate to severe OSA have shown that there is rarely a single anatomic site of blockage (see Figs. 26-1 through 26-3). More commonly, multiple sites of upper airway obstruction occur during episodes of hypopnea and apnea. As stated, the potential upper airway sites of obstruction are somewhat artificially grouped as 1) intranasal; 2) retropalatal; and (3) retroglossal. In addition to taking a history and a physical examination, diagnostic studies to further clarify the anatomic levels of obstruction include the Müller maneuver, which is observed during nasoendoscopic instrumentation; lateral cephalometric radiographs taken during end-tidal volume measurement with the Müller maneuver; helical CT; and magnetic resonance imaging.

Intranasal Site

When a history of chronic obstructive nasal breathing is combined with an intranasal clinical examination, instrumentation (e.g., speculum, endoscope), and radiography (e.g., sinus CT scan), the causes of the intranasal obstruction are generally identified. A thickened, buckled, deviated septum (bone and cartilage), enlarged (hypertrophic) inferior turbinates, an elevated nasal floor, and narrow lateral walls (tight nasal aperture) are frequent causes (see Chapter 10). Occasionally, crooked nasal bones, stenotic external nasal valves (after cleft lip repair), or collapsing internal nasal valves (previous nasal surgery) may also be responsible. Enlarged adenoids or nasal polyps may also be causative factors.

Retropalatal Site

Maxillary hypoplasia either from a known syndrome (e.g., syndromal craniosynostosis, Treacher Collins syndrome, repaired cleft palate) or from a more common developmental dentofacial deformity (e.g., short face growth pattern, long face growth pattern) may be responsible. Enlarged tonsils, excessive lateral parapharyngeal fat pads, and an enlarged floppy soft palate may also be factors.

Retroglossal Site

A retrusive mandible is a frequent component of developmental jaw deformities. As a result of mandibular retrognathia and microgenia, the tongue is retropositioned and elevated. Only rarely is the tongue itself enlarged; rather, it rests in a retro and elevated position as a result of the retrusive mandible. Occasionally an enlarged lingual tonsil will cause retroglossal obstruction. Excess fat deposition in the floor of the mouth will also elevate and retroposition the tongue. Enlarged tonsils and lateral parapharyngeal fat pads may also be contributing factors.

Obstructive Sleep Apnea during Childhood: Diagnosis and Management

"The [American Academy of Pediatrics] guidelines contain the following recommendations for the diagnosis of OSA:

(1) all children should be screened for snoring; (2) complex high-risk patients should be referred to a specialist; (3) patients with cardiorespiratory failure cannot await elective evaluation; (4) diagnostic evaluation is useful in discriminating between primary snoring and OSA, the reference standard being polysomnography; (5) adenotonsillectomy is the first line of treatment for most children, and continuous positive airway pressure is an option for those who are not candidates for surgery or do not respond to surgery; (6) high-risk patients should be monitored as inpatients postoperatively; and (7) patients should be reevaluated postoperatively to determine whether additional treatment is required."[12,57,328]

"This clinical practice guideline is not intended as a sole source of guidance in the evaluation of children with OSA.[15,16,35,46,50,108,110,127,170,216,223,235,296] Rather, it is designed to assist primary care clinicians by providing a framework for diagnostic decision making. It is not intended to replace clinical judgment or to establish a protocol for all children with this condition and may not provide the only appropriate approach to this problem."[223]

Manifestations in Children

Snoring and difficulty breathing during sleep are the most common complaints reported by parents of children with OSA.[54,249,400] However, in contrast with reports of OSA in adults, excessive daytime somnolence is believed to be less common in children, with only 7% of 10% of pediatric patients with OSA experiencing this symptom. Neurocognitive deficits and behavioral manifestations are more frequent in children and may be the result of the chronic exposure to intermittent hypoxemia and sleep disruption caused by sleep fragmentation. Children with OSA are more likely to present with symptoms of hyperactivity, inattentiveness, poor academic performance, and behavioral problems.[30,49,60,112,152,166,229,231,253,254,312] Such symptoms are often attributed to attention-deficit/hyperactivity disorder; treatments prescribed for this disorder (e.g., pharmacologic therapy with stimulants) can actually worsen sleep symptoms.

Diagnostic Criteria in Children

Diagnostic criteria for OSA in adults are typically the product of consensus and often include an AHI of 5 or more as documented by nocturnal PSG as well as evidence of disturbed or unrefreshing sleep, daytime sleepiness, or other daytime symptoms.[313,382] The rationale for specific AHI diagnostic criteria in children as compared with adults suffers from less available data and heterogeneity across studies. Part of the problem is that few studies have been performed to link specified levels of pediatric OSA with adverse outcomes. At present, an AHI or RDI of as low as 1 event/hour is used to identify children with OSA. Pediatric criteria for scoring AHI or RDI are used until the age of 13 years as a matter of routine. According to the most recent American Sleep Disorder Association guidelines, either the pediatric or adult criteria for OSA may be used for adolescent patients who are between 13 and 18 years old at the discretion of the scoring sleep specialist.[12-16] It is also unclear how many events per hour should be considered significant in the adolescent patient as compared with pediatric and adult patients.[5]

Treatment Considerations in Children

Adenotonsillectomy (T&A) is generally considered to be the standard first-line treatment for a child with OSA who does not have complex medical conditions that would make surgery an unacceptable risk.[34,121,124,183,188,220,224,230,232-234,298,317,344,351,355,366,384] A child with OSA should not undergo T&A without receiving a thorough evaluation of the entire upper airway to confirm the actual need for an operation. Nevertheless, the overall cure rate of T&A during childhood is believed to be as high as 82.9%. Studies indicate that, for children with documented OSA and a preoperative RDI of less than 19 events/hour, a T&A will frequently reduce the RDI to less than 5 events/hour. Alternatively, if the preoperative RDI is greater than 19 events/hour, then the T&A has a low probability of reducing the RDI to less than 5 events/hour.[355] Other anatomic causes for the child's OSA should be considered (e.g., maxillomandibular hypoplasia).

A tight nasal inlet is another common cause of upper airway obstruction that may be first recognized during childhood (see Chapter 10). Clinical studies have documented that maxillary arch expansion will improve a tight nasal inlet and thereby decrease nasal airway resistance. Maxillary arch expansion, which is accomplished with the use of a rapid palatal expansion appliance, is commonly carried out during childhood with little morbidity.[8,27,36,79,399] Unfortunately, rapid palatal expansion will only address the one site of obstruction and in a limited way. No studies have confirmed that this approach alone will be effective for OSA. For children in whom T&A or rapid palatal expansion is required but does not lead to the resolution of OSA, evaluation to confirm the additional sites of obstruction should follow and appropriate interventions considered. The option of the administration of CPAP should be entertained, but the overall long-term adherence rate for CPAP is unknown and felt to be problematic in this population. Skeletal reconstruction is likely to be beneficial in a child with a craniofacial anomaly that is known to obstruct the upper airway and in whom OSA has been documented.[17,38,53,270,271,287,341,354,390] For example, maxillary advancement in a child with either Apert or Crouzon syndrome and documented OSA has proven value (see Chapter 30). When a small lower jaw with a retro positioned tongue (i.e., some children with Treacher Collins Syndrome or Pierre Robin sequence) is the cause of OSA, then mandibular advancement can also be helpful (see Chapter 19). Developmental jaw deformities (i.e., long face growth pattern, short face growth pattern, and isolated mandibular

deficiency) occur frequently in the general population, but they often go unrecognized as causes of OSA in children and teenagers (see Chapters 19, 21, and 23). After a developmental jaw deformity has been recognized in a child, OSA should be ruled out.[126,383] Referral to an orthognathic surgeon familiar with OSA is recommended if the PSG is positive (Figs. 26-4 and 26-5).

Managing the Airway during a Surgical Procedure in the Individual with Obstructive Sleep Apnea

A question has been raised regarding the risk of intubation in a morbidly obese individual with a baseline diagnosis of severe OSA. Neligan and colleagues completed a prospective study to assess whether severity of OSA, neck circumference, and BMI were risk factors for difficult intubation in morbidly obese patients.[248] Each study patient (n = 180) underwent preoperative PSG, Mallampati scoring, thyromental distance measurement, mouth opening assessment, and neck circumference measurement. Each study patient was scheduled to undergo a surgical procedure that required orotracheal intubation. A systematic approach to the intubation was developed by the authors that included the placement of the individual into the "ramp" position to facilitate intubation by aligning the three axes: the pharyngeal axis, the laryngeal axis, and the tracheal axis. The ramp position was achieved by placing padding below the individual's back to elevate the head, upper body, and shoulders above the level of the chest. This was judged by positioning the external auditory meatus at the same horizontal level as the sternal notch. Of the 180 patients enrolled in the study, 124 were documented by PSG to have severe OSA (mean AHI, 31.3 events/hour). The median Mallampati score was 2; the mean neck circumference was 43.9 cm; and the mean Cormack and Lehane grade was 1. The incidence of anticipated difficult laryngoscopy, which was defined as a Cormack and Lehane grade of 3 or 4, was 8.3%. Of the study patients with documented OSA (n = 124), only six required three or more intubation attempts, and only 3.3% were judged as being "difficult to intubate." A Mallampati score of 3 or 4 predicted difficult intubation, and a mean neck circumference of 43.9 predicted difficulty with laryngoscopy. The study showed no direct relationship between the diagnosis or severity of OSA and the difficulty of laryngoscopy or intubation. There was no relationship between neck circumference or BMI and difficult intubation. The authors believe that their successful management of intubation requirements in this morbidly obese group related to their meticulous approach to airway management and their technique of using the "ramp" position, which aligns the airway axes and facilitates intubation. Some anesthesiologists prefer to use either a GlideScope (Verathon Medical, Bothell, Wash) or an awake fiber-optic nasotracheal laryngoscopy technique when faced with a morbidly obese individual who requires intubation (see Chapter 11).

Treatment Options for Obstructive Sleep Apnea

Recognizing that a significant subgroup of adults who have been diagnosed with OSA have a chronic illness is essential when considering treatment options. In general, obese adults with OSA should be thought of in a similar way to those with diabetes or hypertension. For these individuals, the total elimination of the disease is not generally feasible.[63,147,169,344] The goal of any treatment modality in this situation is to improve or control the symptoms and the health risks by reducing the severity. A clear exception to this way of thinking is in the individual with a small-lumen upper airway that is primarily the result of retrognathic jaws. For these individuals, who make up approximately one third of patients with OSA, the correction of the jaw deficiency is expected to be successful for most.[29,44,82,144,149,186,197,283,285,311,312]

A review of the literature that addresses the management of OSA confirms that a plethora of publications discuss a spectrum of medical and surgical treatment options.[181,207] More than a dozen "non-surgical" treatment options are mentioned, including palatal, tongue, and jaw training exercises; controlled sleep positioning; spray medications to reduce soft-tissue edema or to improve muscle tone; the use of a spectrum of oral appliances that have been designed to protrude the lower jaw; and the use of CPAP delivered through a variety of occlusive devices over the mouth and nose. The majority of these treatment recommendations (with the exception of CPAP) are empiric and frequently recommended as "simple" options in an attempt to avoid surgery or the need for CPAP. In addition, more than a dozen surgical options are offered with the intention of affecting either a specific region of the pharynx or a tissue type within the head and neck (e.g., external nasal valves, internal nasal valves, nasal septum, nasal turbinates, soft palate, adenoids, uvula, tonsillar pillars, tonsils, tongue, maxilla, mandible, chin, hyoid bone). Ideally, to ensure compliance with the recommended treatment, 1) the medical or surgical approach should have a biologic basis that is directed at the sites of pathology; 2) a reasonable probability of success should be anticipated; 3) an acceptable level of risk should be clarified; and 4) a realistic level of patient acceptance should be expected.

Bariatric Surgery

Rasheid and colleagues completed a prospective study in a consecutive series of patients (n = 100) that underwent gastric bypass for the management of obesity to determine the effects of the surgery on OSA.[290] Before surgery, all patients underwent PSG. The mean preoperative RDI was 40 ± 4. Thirteen patients had no OSA, 29 had mild OSA, and 58 had moderate to severe OSA. At 6 months after surgery, patients' BMIs had improved (38 ± 1 kg/m^2 versus 54 ± 1 kg/m^2), and so had their ESS scores (6 ± 1 versus

Text continued on p. 1008

• **Figure 26-4** A 16-year-old boy was referred by his pediatrician for surgical evaluation. He had a history of heavy snoring, restless sleeping, daytime somnolence, attention-deficit/hyperactivity disorder and other behavioral problems, and poor school grades. An attended polysomnogram documented an apnea–hypopnea index of 30 events/hour. Head and neck examination confirmed a normal-sized and functioning soft palate and tongue. The tonsils and adenoids were not enlarged. The intranasal cavity was obstructed (septal deviation and inferior turbinate hypertrophy). The soft palate was resting close to the posterior pharyngeal wall as a result of maxillary retrusion. The tongue was retropositioned as a result of a retrognathic mandible. The patient had previously undergone 2 years of orthodontics and achieved a Class I canine and molar occlusion. The anterior and posterior facial heights were relatively normal. After consultation with his medical and dental team (general dentist, orthodontist, pediatrician, and sleep specialist), the patient agreed to a surgical approach. Orthodontic appliances were placed to protect the periodontium, and he underwent jaw and intranasal surgery. The patient's procedures included maxillary Le Fort I osteotomy (horizontal advancement +10 mm); bilateral sagittal split ramus osteotomies (horizontal advancement +10 mm); osseous genioplasty (horizontal advancement +10 mm); and septoplasty and inferior turbinate reduction. Three months after surgery, he underwent an attended polysomnogram that confirmed the resolution of the obstructive sleep apnea with an apnea–hypopnea index of 2.6 events/hour. He no longer snored or experienced restless sleep. Daytime fatigue improved, as did his behavioral problems and his schoolwork. **A,** Frontal views with smile before and after surgery. **B,** Oblique facial views before and after surgery. **C,** Profile views before and after surgery.

• **Figure 26-5** A 15-year-old boy was referred by his pediatrician and arrived with his parents for the surgical evaluation of documented obstructive sleep apnea. He had a history of heavy snoring, restless sleeping, and daytime somnolence. He was diagnosed with attention-deficit/hyperactivity disorder when he was 3 years old, and his school grades are poor. An attended polysomnogram confirmed an overall apnea–hypopnea index of 17 events/hour. In the supine position, his apnea–hypopnea index was 39 events/hour with desaturation to 78%. Head and neck examination confirmed a normal-sized and functioning soft palate and tongue. The tonsils and adenoids had previously been removed, and the intranasal cavity was obstructed (septal deviation and inferior turbinate hypertrophy). The soft palate was resting close to the posterior pharyngeal wall, and the tongue was retropositioned. Both the maxilla and the mandible were deficient in horizontal projection, which explained the reduced airway space. The anterior facial height was mildly deficient. The patient previously underwent orthodontics and had achieved a Class I canine and molar occlusion. In consultation with medical and dental specialists (general dentist, orthodontist, pediatrician, and pulmonologist), the patient agreed to a surgical approach. Orthodontic appliances were placed to protect the periodontium, and he underwent jaw and intranasal surgery. The patient's procedures included maxillary Le Fort I osteotomy (horizontal advancement +10 mm); bilateral sagittal split ramus osteotomies (horizontal advancement +10 mm); osseous genioplasty (horizontal advancement); and septoplasty and inferior turbinate reduction. Three months after surgery, he underwent an attended polysomnogram that confirmed the resolution of the obstructive sleep apnea with an apnea–hypopnea index of 0.9 events/hour and a maximum desaturation of 92%. He was no longer snoring or experiencing restless sleep. His daytime fatigue, behavioral problems, and schoolwork all improved. **A,** Frontal views with smile before and after surgery. **B,** Oblique facial views before and after surgery. **C,** Profile views before and after surgery.

12 ± 0.1). There were also a significant reductions in minimum desaturations during sleep as well as improvements in sleep efficiency. A shortcoming of the study was its conclusion at just 6 months after surgery.

A study by Pillar and colleagues describes the long-term follow up of patients with regard to both weight loss and upper airway findings after bariatric surgery.[273] At 4 months after surgery, there was a significant improvement in the AI from 45 events/hour to 11 events/hour. Over a 7-year time frame, the AI regressed from a mean of 11 events/hour back up to 24 events/hour; however, the AI remained at a much lower level (24 events/hour) than it was before surgery (45 events/hour). In their report, the effectiveness of bariatric surgery was to reduce the mean BMI from 40 kg/m^2 (i.e., morbid obesity) to a mean BMI of 35 kg/m^2 (i.e., obesity) at 7 years after surgery. During the same time frame, the mean AI was reduced from 45 events/hour down to 24 events/hour. Other researchers have also studied the long-term effects of bariatric surgery on patient health.[52,97,116,134]

Continuous Positive Airway Pressure Option

The use of CPAP for OSA was first reported in 1981. Since its introduction, it has become the reference standard for non-surgical management.[43,65,66,71,105,107,114,132,148,159,160,178,181,217,236,267,356,357] With this method, positive pressure can be continuously delivered through a sealed nasal or mouth mask that the patient wears while sleeping. The positive pressure has the potential to pneumatically splint open the whole pharyngeal airway by preventing the soft palate and the tongue from making a seal with the posterior pharyngeal mucosa (i.e., it acts as a counteracting force to the aforementioned collapsing force in the patient with an anatomic predisposition for airway obstruction). The pressure required to achieve this goal is titrated at a sleep laboratory during PSG. CPAP is a sound, evidence-based treatment option that has been shown to be effective when it is used correctly and consistently throughout the night as well as night after night throughout the patient's life. If CPAP is used in this way, it will decrease daytime sleepiness and therefore likely improve the patient's mood and quality of life. The discomfort and difficulty associated with the use of CPAP (e.g., drying of the nasal and oral mucous membranes, dislodgment during sleep, noise, inconvenience when transporting the unit, social displeasure, feelings of claustrophobia) makes long-term compliance a clear problem. Even when defining an acceptable CPAP compliance rate of just 4 hours per night for 70% of nights, only a limited percentage of patients (depending on the study reviewed) who consider themselves users of CPAP are adherent. This does not take into account the significant number of those with OSA who either will not consider trying CPAP or those who have tried it but then refuse to use it. Furthermore, this "acceptable compliance rate" represents only approximately 50% of functional sleep time.[77,252,291,318,385] Sleep medicine clinicians continue to appreciate the complexity of the disorder (i.e., complex chemoreceptor apnea and apnea-related behavioral derangements), and they now acknowledge the inability of a majority of patients to stick with CPAP for the long term, even if they do use it for the short term. Nevertheless, all individuals should be advised of the availability of CPAP and encouraged to consider it.

The American Heart Association/American College of Cardiology Foundation released a position statement about the effects of sleep apnea on cardiovascular disease.[133] The organizations summarized published studies that confirmed the moderate and variable effects of CPAP therapy for OSA on blood pressure. They concluded that individuals with more severe OSA, difficult-to-control hypertension, and better CPAP compliance are likely to have more substantial blood pressure reduction with CPAP. They also recommended that, for those hypertensive patients who were either not willing to use CPAP or not compliant, other effective methods of managing OSA should be considered (e.g., MMCA).

A sleep medicine specialist consult is often beneficial for the patient to maximize his or her education about the disease process and its effects (both behavioral and pathophysiologic) and to explore the CPAP option. Likewise, all patients should be advised of potential surgical alternatives that may apply to them. An evaluation by a surgeon who is familiar with current literature and treatment modalities is beneficial to fully explore non-CPAP options. Clearly, not all surgical options have equal success for each patient. A frank discussion with a knowledgeable surgeon regarding the patient's specific potential benefit-to-risk ratio for each surgical procedure is essential (see discussion to follow).

Oral Appliance Option

The objective of an oral appliance (OA) for the treatment of OSA is to mechanically reposition and hold the mandible in a protruded (forward) location during sleep.[259] As the mandible moves forward, so does the tongue. An effective OA must prevent the sealing of the tongue to the posterior pharyngeal mucosa, thereby limiting obstruction at that site.[374] The upper airway response to oral appliances varies among individuals. It has been stated that up to 50% of individuals with OSA who use an oral appliance will "respond to some extent."[218] Unfortunately, no matter how technically precise the OA is, it can only affect the retroglossal site.[213,325] Most individuals with moderate to severe OSA have obstruction at multiple sites.[377] According to published research, the median compliance rate with an OA after 1 year is 39% with a range of 4% to 82%, depending on the study reviewed.[96] Frequently stated potential long-term negative effects of OAs include: tooth movement with changes in occlusion; injury to the periodontium; excessive salivation or dry mouth; and temporomandibular disorders including masticatory muscle discomfort.[308,310] Other stated reasons for non-compliance include the insufficient reduction of snoring, continued OSA, or social concerns during use. Almeida and colleagues reviewed a series of patients (n = 70) who used OAs to treat snoring or OSA for more than 5 years.[294] The authors found that 44% of those patients had suffered unfavorable occlusal, dental, or temporomandibular joint changes. In research that was carried out by Pancer and colleagues, 14% of study patients (n = 106) were found to have evidence of occlusal changes with the use of an OA for the treatment of OSA.[261] The most common pathologic tooth movements were lingual tipping of the maxillary incisors, proclination of the mandibular incisors, and anterior shifting of the lower first molars. Although some patients were unaware of the occlusal changes, many were acutely bothered by the "shifts" (alterations) in their bites. Bondenmark and Bondenmark and Lindman observed patients (n = 32) after 2 years of continuous OA use.[31,32] Occlusal changes were documented on lateral head radiographs in the study patients. The authors hypothesized that temporomandibular joint remodeling had occurred. To

review, the use of OAs is not generally therapeutic for moderate to severe OSA, and OAs are often not well tolerated in the long term.

An often-stated objective of an OA is for use as a therapeutic trial to determine if a patient would be a candidate for lower jaw surgical advancement. If patients respond to an effective OA, they are said to likely respond in a similar way to mandibular advancement surgery. This is not necessarily the case, because many OAs are designed to position the mandible into a full Class III malocclusion. To achieve the same degree of mandibular advancement, both upper and lower jaw surgery would be required.

Indications for Upper Airway Surgery and Spectrum of Options

Surgery for OSA is indicated when applicable conservative therapies are unsuccessful, intolerable, or unacceptable to the patient with underlying specific anatomically correctible abnormalities that are causing the OSA.[76,80,81,139,193-195,198,202,280,282,285,304,307,358,375] Unfortunately, the use of either CPAP or an OA requires continued personal application of a mechanical device. Likely for this reason, neither is consistently well tolerated or found to be acceptable to the patient in the long run. Indications for surgery to treat OSA are often stated to be a failure of medical management in the individual with one of the following symptoms:

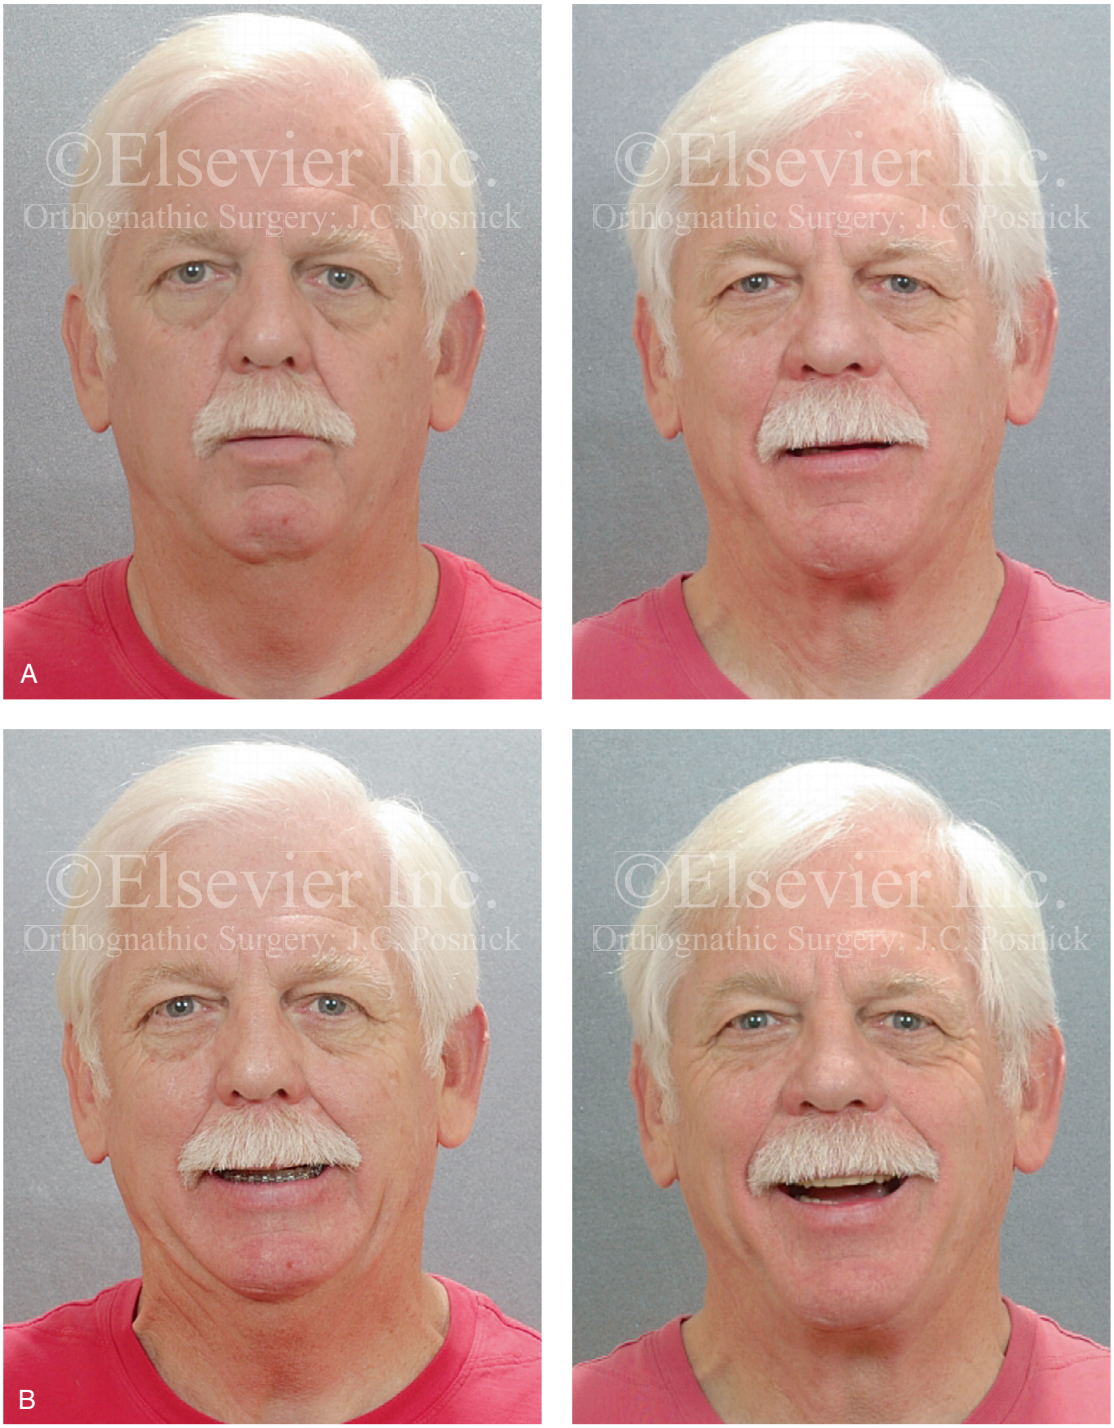
- Excessive daytime sleepiness as a result of OSA
- RDI of more than 20 events/hour
- RDI of less than 20 events/hour but with marked excessive daytime sleepiness
- Oxygen desaturations of less than 90% with apnea events
- Documented hypertension, arrhythmia, or both believed to be triggered by OSA
- Negative esophageal pressures (i.e., >−10 cm of water)
- Anatomic abnormalities of the upper airway (i.e., jaw deformity, fixed intranasal obstructions, chronically enlarged tonsils, enlarged floppy soft palate) that result in apnea events

Although tracheostomy may be considered a way of achieving a "cure" for OSA because it completely bypasses all obstructions of the upper airway, secondary medical and social problems as a result of the tracheostomy cannot be overlooked.[242,368,369] In general, this option is only considered for extreme cases (e.g., newborns or infants with congenital deformities such as the severe retrognathia seen with Treacher Collins syndrome) or as a temporary solution.

Uvulopalatopharyngoplasty (UPPP)—the surgical removal of the uvula, additional parts of the soft palate, the pharyngeal pillars, and the tonsils—to open the airway was originally described by Fujita in 1981.[98,99] Although the effectiveness of this approach for the resolution of OSA is limited, it continues to be an often mentioned treatment option, because it is considered by some to be minimal surgery or a first treatment step (see Figs. 26-3 and 26-6).[2,40,58,93,119,189,272,298,334,342] The reason for its limited success is because it addresses only the retropalatal site, and it does so in an incomplete way.[209] In general, it will shorten the soft palate, but it may also result in a thicker and narrower retropalatal pharyngeal airway as a result of scarring. Interestingly, although improvements in snoring generally occur after UPPP, over time, the AHI actually increases in approximately 30% of patients. This is called *silent apnea;* the relief of the snoring may lead the individual to falsely believe that his or her apnea has also gone away. Realistically, UPPP is expected to be therapeutic only for those with massive soft-tissue redundancy of the pharynx and without concomitant intranasal and retroglossal obstruction.[95,192,204,336,335,391] When either the adenoids, the tonsillar tissue, or the soft palate is significantly hypertrophic or redundant and causing physical blockage of the upper airway, surgery to remove this excessive tissue should be considered. In the absence of a specific syndrome or anomaly that causes increased tongue volume (e.g., Proteus syndrome, vascular anomalies, Beckwith-Wiedemann syndrome), this is rarely a cause of OSA.[47,353] Frequent concerns after intrapharyngeal soft-tissue reduction procedures (e.g., UPPP, tonsillectomy, tongue reduction) include perioperative edema (airway compromise); moderate to severe pain for 2 to 3 weeks; limited success with a single-site approach for the resolution of OSA; velopharyngeal reflux; velopharyngeal insufficiency; pharyngeal scarring (stenosis); and silent apnea.[173,226]

If the maxilla and the mandible are retrusive then consideration should be given to the surgical advancement of these structures to correct the baseline anatomic deformity .[193-195,201,215,277,345,398] MMCA has been shown to enlarge the pharyngeal and hypopharyngeal airway by physically expanding the whole facial skeletal framework (see Figs. 26-4 and 26-7 through 26-14). Because the lateral pharyngeal walls are dynamic, the skeletal expansion also tightens the soft tissues; this subsequently decreases lumen collapsibility. This skeletal approach address's the "small airway" via an extrapharyngeal operation with minimal risk of early postoperative edema-induced upper airway compromise or long-term pharyngeal dysfunction. This operation is also thought to enhance the neuromuscular tone of the pharyngeal dilator musculature (e.g., tensor veli palatini, genioglossus). These anatomic facts explain the highly successful outcomes that have been documented after MMCA. Frequent short-term (perioperative) concerns in the adult patient after MMCA are most often related to: altered occlusion; dysesthesia (sensory loss); limited mouth opening; adjustment to the change in facial appearance; and the downtime required for recovery (see Chapter 25). If septal deviation or thickening or inferior turbinate enlargement or hypertrophy results in significant nasal airway resistance, then these abnormalities can be addressed simultaneously with MMCA (see Chapter 10).[94,191,247,275,276,278] The medical risks associated

Text continued on p. 1045



• **Figure 26-6** A 59-year-old man was referred by his otolaryngologist/head and neck surgeon to discuss further surgical options for the management of documented obstructive sleep apnea. He had already undergone uvulopalatopharyngoplasty, septoplasty, and inferior turbinate reduction. The procedures helped his snoring, but a postsurgery attended polysomnogram confirmed a respiratory disturbance index of 51 events/hour, with desaturations reaching as low as 82%. The patient was also seen by a pulmonary sleep specialist and a cardiologist; mild concentric left ventricular hypertrophy and mild pulmonary hypertension we found. The patient was unable to tolerate continuous positive airway pressure on a regular basis. He lost 20 pounds and was exercising regularly, but this did not resolve his obstructive sleep apnea. Examination confirmed a short face growth pattern with maxillomandibular deficiency (decreased vertical height and limited horizontal projection). During his teenage years, the patient had undergone orthodontic treatment that included four bicuspid extractions. He was now showing signs of periodontal deterioration, and he had a posterior crossbite on the left side. He underwent evaluation by a periodontist, a restorative dentist, and an orthodontist. He agreed to a comprehensive dental rehabilitation approach, with a primary interest in achieving an improved upper airway with the resolution of the obstructive sleep apnea. The sleep specialist and the otolaryngologist were also supportive of this approach. The patient's procedures included maxillary Le Fort I osteotomy (horizontal advancement +10 mm and vertical lengthening +5 mm) with interpositional graft; bilateral sagittal split osteotomies of the mandible (horizontal advancement +12 mm); osseous genioplasty (horizontal advancement); redo septoplasty; and anterior arch soft-tissue procedures (cervical flap elevation, fat removal and platysma muscle plication). Three months after surgery, an attended polysomnogram was carried out, which confirmed a respiratory disturbance index of less than 5 events/hour with the lowest desaturations at 90%. Subjectively, the patient feels that his snoring has resolved, his nighttime sleeping is improved, and his daytime somnolence is greatly diminished. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

• **Figure 26-7** A 51-year-old man was referred by a neurologist to discuss surgical options for the management of documented obstructive sleep apnea. He had heavy snoring, restless sleeping, and significant daytime somnolence. A recent attended polysomnogram confirmed a respiratory disturbance index of 41 events/hour with oxygen desaturation of as low as 80%. A continuous positive airway pressure titration study was effective at 12 cm of pressure; however, the patient was not able to tolerate continuous positive airway pressure. Intranasal examination confirmed a deviated septum and hypertrophic inferior turbinates. The patient's tonsils and adenoids were minimal in size. The soft palate functioned well, but the uvula was enlarged. The tongue was of normal size and function. During his teenage years, the patient had undergone orthodontic treatment, and he had a Class I deep bite. Examination confirmed a short face growth pattern that involved deficient vertical height and limited horizontal projection. Consultations with a sleep specialist, an internist, a general dentist, an otolaryngologist/head and neck surgeon, and an orthodontist were carried out. The patient agreed to a surgical approach that included orthodontics as needed to protect the periodontium. The procedures included maxillary Le Fort I osteotomy (horizontal advancement +10 mm and vertical lengthening +8 mm) with interpositional allograft; bilateral sagittal split osteotomies of the mandible (horizontal advancement); osseous genioplasty (horizontal advancement); uvulectomy; and septoplasty and inferior turbinate reduction. After surgery, the patient's snoring was resolved, his nighttime sleeping improved, and his daytime somnolence was greatly diminished. A 1-year postoperative polysomnogram confirmed a respiratory disturbance index of 13 events/hour. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

Continued

• **Figure 26-8** A 50-year-old woman was referred by her general dentist to an orthodontist and then for surgical evaluation. She had a mandibular deficiency and a constricted upper jaw width growth pattern that resulted in a Class II deep-bite excess overjet malocclusion. Over the years, there was destruction to the dentition and the periodontal apparatus with generalized bone loss and gingival recession. She was now under the care of a restorative dentist and a periodontist. To resolve the malocclusion, maxillary expansion and mandibular advancement in combination with orthodontics were recommended. As part of her referral to this surgeon, a history was taken that documented heavy snoring, restless sleeping, and daytime somnolence. An attended polysomnogram confirmed a respiratory disturbance index of 42.7 events/hour. There was intranasal site obstruction as a result of septal deviation and inferior turbinate enlargement. There was also retropalatal obstruction caused by maxillary retrusion and a retropositioned tongue that resulted from mandibular retrusion. The soft palate and the tongue were of normal size and function. There were minimum tonsil and adenoid structures. Continuous positive airway pressure was tried but not well tolerated. Surgery was agreed to in combination with orthodontics to improve the malocclusion and open the airway. The procedures that were carried out included maxillary Le Fort I osteotomy (horizontal advancement +7 mm, vertical lengthening +3 mm, and arch form correction); bilateral sagittal split osteotomies of the mandible (horizontal advancement +12 mm); osseous genioplasty (horizontal advancement); septoplasty and inferior turbinate reduction; and an anterior approach to the neck (cervical flap elevation, supraplatysmal defatting, and vertical platysma muscle plication). Subjectively, there was good relief of snoring, restless sleeping, and daytime fatigue. One year after surgery, an attended polysomnogram confirmed the resolution of the obstructive sleep apnea, with a respiratory disturbance index of 1.9 events/hour. **A,** Frontal views in repose before and after treatment. **B,** Oblique facial views before and after treatment. **C,** Profile views before and after treatment.

• **Figure 26-9** A 25-year-old man was referred by his general dentist to an orthodontist and then to this surgeon for the evaluation of a dentofacial deformity. Examination confirmed a maxillary deficiency and a relative mandibular excess growth pattern; this resulted in a severe Class III negative overjet anterior open-bite malocclusion. The maxillomandibular deformities had a negative impact on the patient's speech articulation, swallowing, chewing, breathing, and lip closure/posture. The patient's history confirmed lifelong obstructed nasal breathing, restless sleeping, heavy snoring, and daytime fatigue. An attended polysomnogram was carried out and documented a respiratory disturbance index of 14 events/hour, with desaturations of as low as 87%. The patient underwent additional evaluations by a sleep specialist, an otolaryngologist, a speech pathologist, a restorative dentist, and a periodontist. He agreed to a comprehensive surgical and dental rehabilitative approach, and his periodontal treatment was followed by orthodontic decompensation. The patient's procedures included maxillary Le Fort I osteotomy in segments (horizontal advancement +10 mm, arch expansion and minimal clockwise rotation) with interpositional graft; bilateral sagittal split osteotomies of the mandible (horizontal advancement +4 mm and counterclockwise rotation); osseous genioplasty (horizontal advancement); and inferior turbinate reduction and septoplasty. The patient experienced relief of his snoring, improvements in his sleep quality, less daytime fatigue, and improved breathing during the day. Interestingly, the 4-month postoperative attended polysomnogram indicated only mild reduction of the sleep indexes. Reevaluation by the sleep specialist recommended the avoidance of supine sleep, with no need for further treatment. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

• **Figure 26-10** A 37-year-old man was referred to this surgeon with a request to have his chin implant removed because he was displeased with the aesthetic results. When he was 20 years old, he had undergone a chin augmentation (silicone implant) in an attempt to camouflage the small lower jaw profile. Ten years later, he underwent four bicuspid extractions and orthodontic alignment to improve the occlusion. He had undergone a septorhinoplasty procedure, but he was still experiencing continued difficulty breathing through the nose. During the patient's referral to this surgeon, an examination confirmed maxillomandibular deficiency. He was recognized as having a short face growth pattern with decreased lower anterior facial height and limited facial projection. There was an accentuated labiomental "lip curl" and a "button appearance" of the chin. It was clear that the patient suffered with snoring, restless sleeping, and excessive daytime fatigue. An attended polysomnogram confirmed a respiratory disturbance index of 16 events/hour, with desaturations of 89%. A titration study confirmed the need for 12 cm of water pressure to reduce the respiratory disturbance index to 3 events/hour. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

• **Figure 26-10, cont'd** The use of continuous positive airway pressure was attempted, but the patient found it to be uncomfortable and difficult to use. Consultations with a sleep specialist, an otolaryngologist, and an orthodontist confirmed the advantage of an intranasal and orthognathic surgical approach. The patient agreed to perioperative orthodontics and surgery to improve the airway and facial appearance. The patient's procedures included maxillary Le Fort I osteotomy (horizontal advancement +9 mm, vertical lengthening +5 mm) and interpositional grafting; bilateral sagittal split osteotomies of the mandible (horizontal advancement +12 mm); removal of the chin implant; osseous genioplasty (horizontal advancement and vertical lengthening) with interpositional grafting; reduction of the inferior turbinates; redo septoplasty; and an anterior approach to the neck (cervical flap elevation, suprapla-tysmal defatting, and vertical platysma muscle plication). As a result of the procedures, the patient experienced relief of his snoring, improved sleep quality, diminished daytime fatigue, and improved breathing during the day. Six months after surgery, he underwent an attended polysomnogram that indicated a normal sleep study, with no snoring or apnea events. **C,** Oblique facial views before and after surgery. **D,** Profile views before and after surgery.

• **Figure 26-11** A 33-year-old man was referred by his orthodontist for the surgical evaluation of a dentofacial deformity. Examination confirmed a long face growth pattern with a Class III anterior open-bite malocclusion. During the mixed dentition, the patient underwent growth modification and orthodontic treatment that included the use of a Frankel appliance, a chin cup, and rapid palatal expansion. By the end of high school, he was left with a residual anterior open bite, a constricted maxillary arch, and a gummy smile. When he was 29 years old and had a lifelong history of heavy snoring, difficulty sleeping at night, and daytime fatigue, he underwent a sleep study. The polysomnogram revealed moderate obstructive sleep apnea with a respiratory disturbance index of 16 events/hour and oxygen desaturations down to 86%. A continuous positive airway pressure titration study confirmed the need for 10 cm of water pressure to resolve the respiratory events. The current head and neck examination documented a deviated septum; enlarged inferior turbinates; an elevated nasal floor; narrow pyriform rims; a soft palate close to the pharyngeal wall; and a retropositioned tongue. The tonsils were not enlarged, and the tongue and soft palate were of normal size. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

Continued

• **Figure 26-11, cont'd** The patient hoped to achieve improved breathing during the day, better sleeping at night, and resolution of his obstructive sleep apnea. He also wanted correction of his malocclusion, improvements in his lip closure/posture, and an enhanced profile and smile. He agreed to a comprehensive orthodontic and surgical approach. With the orthodontic relief of his dental compensation, intranasal, orthognathic, and facial surgery was carried out. The patient's procedures included maxillary Le Fort I osteotomy in three segments (horizontal advancement +8 mm, vertical shortening –4 mm, and arch expansion); bilateral sagittal split osteotomies of the mandible (horizontal advancement +12 mm and counterclockwise rotation); osseous genioplasty (horizontal advancement and vertical shortening); reduction of the inferior turbinates, septoplasty, and recontouring of the nasal floor; and an anterior approach to the neck (cervical flap elevation, supraplatysmal defatting, and vertical platysma muscle plication). He experienced the relief of his snoring, improvement in his quality of sleep, the ability to breathe through the nose during the day, and less daytime fatigue. He had not yet undergone a formal posttreatment polysomnogram. **C,** Oblique facial views before and after surgery. **D,** Profile views before and after surgery.

• **Figure 26-12** A 32-year-old man was referred by his internist and otolaryngologist/head and neck surgeon to discuss further surgical options for the management of document obstructive sleep apnea. An attended polysomnogram confirmed a respiratory disturbance index of 56 events/hour, with oxygen desaturations reaching as low as 84%. The patient's sleep efficiency was reduced to 46%. He underwent a split study that confirmed the need for 8 cm of continuous positive airway pressure to significantly reduce the respiratory disturbance index. He was unable to effectively use the continuous positive airway pressure device as a result of claustrophobia, excessive noise, and poor mask fit. Since his early childhood years, the patient was known to have a jaw deformity with malocclusion. He underwent 2 years of orthodontic treatment when he was 12 to 14 years old; this resulted in improvement of the occlusion but residual jaw deformity. Examination confirmed a short face growth pattern with maxillomandibular deficiency (decreased vertical height and limited horizontal projection). The tonsils were not inflamed, but they were moderately enlarged, and the uvula was mildly long and floppy. The tongue was of normal size, the septum was straight, and the inferior turbinates were enlarged. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

Continued

• **Figure 26-12, cont'd** The patient underwent evaluation by a restorative dentist, an orthodontist, a sleep specialist, an otolaryngologist/head and neck surgeon, and an internist. His primary motivations were to achieve an improved airway and to resolve his obstructive sleep apnea. He was also interested in improved profile aesthetics and long-term dental health. We discussed potential benefits of tonsillectomy and of the reduction of the size of the soft palate, but he preferred a skeletal approach, thus reserving the option of soft-tissue reduction if needed as a secondary procedure. With orthodontic appliances in place, the patient's procedures included maxillary Le Fort I osteotomy (horizontal advancement +10 mm and vertical lengthening +4 mm) with interpositional allogenic graft; bilateral sagittal split osteotomies of the mandible (horizontal advancement +12); osseous genioplasty (horizontal advancement); and inferior turbinate reduction. He experienced relief of his snoring, improvement in his quality of sleep, better breathing during the day, and less daytime fatigue. Three months postoperatively, he underwent an attended polysomnogram. Interestingly, after surgery, he chose to sleep with his lips taped together out of the belief that this improves sleep hygiene, including air humidification. Thus, the sleep study was carried out with the patient's lips taped together. An overall respiratory disturbance index of 15 events/hour was documented, with average desaturations to 95%. **C,** Oblique facial views before and after surgery. **D,** Profile views before and after surgery.

• **Figure 26-13** A 43-year-old man was referred by a restorative dentist to an orthodontist and then for surgical evaluation of a dentofacial deformity characterized by maxillomandibular deficiency. Despite orthodontic treatment (including four bicuspid extractions when the patient was a teenager), there remained a Class III negative overjet bilateral posterior cross-bite malocclusion. A degree of labial bone loss and gingival recession was appreciated. Earlier during his life, the patient's nose was broken during a sports injury, and he had since experience chronic obstructive breathing. Examination confirmed a deviated septum and inferior turbinate enlargement. The tonsils, the tongue, and the soft palate were essentially normal; the uvula was somewhat enlarged. He admitted to heavy snoring, restless sleeping, and excessive daytime fatigue. A sleep study confirming a respiratory disturbance index of 37 events/hour with desaturations reaching a low of 86%. The patient was fitted with a continuous positive airway pressure device (8 cm of water pressure per hour) as temporary treatment while his orthodontics were initiated. After the orthodontic relief of dental compensation, surgery was carried out. The patient's procedures included maxillary Le Fort I osteotomy in two segments (horizontal advancement +10 mm, vertical lengthening –2 mm, and arch expansion) with allogenic interpositional grafting; bilateral sagittal split osteotomies of the mandible (horizontal advancement +13 mm and counterclockwise rotation); osseous genioplasty (horizontal advancement); inferior turbinate reduction and septoplasty; and an anterior approach to the neck (cervical flap elevation, supraplatysmal defatting, and vertical platysma muscle plication). After surgery, there was an immediate relief of the patient's snoring as well as improvements in his quality of sleep, his ability to breathe through his nose, his concentration, and his daytime fatigue. The 6-month postoperative attended polysomnogram confirmed a reduction in the respiratory disturbance index to 10 events/hour. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

Respiratory disturbance index = 37/hr

Respiratory disturbance index = 10/hr

• **Figure 26-13, cont'd** **F,** Articulated dental casts that indicate analytic model planning. **G,** Lateral cephalometric radiographs before and after surgery.

• **Figure 26-14** A 34-year-old man was referred by his orthodontist for a surgical evaluation of a longstanding dentofacial deformity with malocclusion. Examination confirmed a long face asymmetric Class III growth pattern with an anterior open-bite, negative overjet, posterior crossbite malocclusion. During the mixed dentition, growth modification maneuvers were attempted. Compensatory orthodontic mechanics were then used but did not result in correction. A residual gummy smile with lip incompetence and asymmetric Class III negative overjet malocclusion remained. The patient had undergone septoplasty and tonsillectomy when he was 20 years old in an attempt to improve the airway but without success. At referral to this surgeon, the patient's history confirmed ongoing heavy snoring, difficulty sleeping at night, an inability to breathe through the nose, and excessive daytime fatigue. The patient underwent an attended polysomnogram that confirmed a respiratory disturbance index of 19 events/hour, with desaturations reaching as low as 84%. A continuous positive airway pressure titration study was carried out, and the use of continuous positive airway pressure was attempted; however, as a result of side effects, it was not practical for this patient. A head and neck examination documented a severely deviated septum, enlarged inferior turbinates, an elevated nasal floor, narrow pyriform rims, a soft palate that was close to the pharyngeal wall, and a retropositioned tongue. The tonsils had previously been removed, and the tongue and soft palate were of normal size. **A,** Frontal views in repose before and after surgery. **B,** Frontal views with smile before and after surgery.

• **Figure 26-14, cont'd** The patient hoped to achieve improved breathing during the day, better sleeping at night, and the relief of excessive daytime fatigue. He also desired the correction of his malocclusion to improve swallowing, speech, chewing, and lip closure as well as to enhance his profile and smile aesthetics. He agreed to a comprehensive orthodontic and surgical approach. No extractions were required, and the orthodontic relief of dental compensation was accomplished. The patient's jaw and intranasal procedures included maxillary Le Fort I osteotomy in three segments (horizontal advancement +8 mm, vertical shortening –1.0 mm, dental midline correction, clockwise rotation of 2 mm, and arch expansion) with interpositional graft; bilateral sagittal split osteotomies of the mandible (horizontal advancement +2 mm); osseous genioplasty (vertical shortening and minimal horizontal advancement); and inferior turbinate reduction, septoplasty, and recontouring of the nasal floor. The patient experienced immediate relief of his snoring as well as improvements in quality of sleep, ability to breathe through the nose during the day, and daytime fatigue. An attended polysomnogram was carried out 4 months after surgery and demonstrated the relief of apnea in all sleep positions other than supine. When sleeping supine, mild obstructive sleep apnea remained, but there were no longer any significant desaturations. **C,** Oblique facial views before and after surgery. **D,** Profile views before and after surgery.

with general anesthesia in conjunction with orthognathic and intranasal procedures are expected to be greater among adults with OSA than among teenagers. These risks may include the potential for stress to the cardiovascular, renal, and respiratory systems (see Chapters 11 and 16).

The advantage of a combined intranasal and jaw operation for the individual with OSA is that, like CPAP, such a procedure effectively addresses all of the obstructing upper airway sites simultaneously (i.e., intranasal, retropalatal, and retroglossal). Straightening the septum; reducing the inferior turbinates; widening the maxilla and the piriform rim (i.e., segmental Le Fort I osteotomy), if indicated; and recontouring (deepening) the nasal floor, if indicated—in combination with MMCA—dramatically opens the whole upper airway. Posnick and colleagues have confirmed that jaw and intranasal procedures can be carried out simultaneously without increasing complications.[278]

If the individual requires tonsillectomy, UPPP, or both, then the procedures are carried out separately from the jaw and intranasal operations. This is done because the national reported incidence of significant postsurgical bleeding after UPPP or tonsillectomy is 2% to 4%. In this author's practice, amputation of an elongated uvula (i.e. without the resection of the soft palate) when indicated to further improve the retropalatal airway site is frequently carried out simultaneously with the jaw and intranasal surgery; this is relatively free of risk, and it will avoid the need for a second round of surgery, anesthesia, and recovery.

The Maxillary–Mandibular–Chin Advancement Option

Background

Clinicians now recognize that maxillomandibular deficiency results in reduced pharyngeal airway dimensions and that it can, on its own, lead to or be an additive factor for OSA in both children and adults (see Figs. 26-4 through 26-14).[11,17,154,158,162,184,239,271,285,341,354,363,380,383,390] Mandibular advancement was first suggested in 1979 by West and colleagues as an alternative to tracheostomy for the treatment of OSA.[181] By the early 1980s, Riley and colleagues further documented the value of mandibular advancement surgery that is specifically carried out for the treatment of OSA.[297,306] They advocated simultaneous maxillary and mandibular advancement (MMA) to open the upper airway and to diminish apnea episodes among appropriate individuals with OSA. This surgical approach has consistently been shown to be a highly effective modality for opening the whole upper airway passage for individuals with OSA* (see Figs. 26-4 through 26-14).

Prinsell and colleagues stated the following: "MMA surgery for obstructive sleep apnea syndrome is a highly successful and potentially definitive primary single-stage surgery that may result in a significant reduction in OSA-related health risks, as well as financial savings for the health care system."[284,285] **Li and colleagues** reached the same conclusion and stated the following: "Maxillomandibular advancement surgery is the most effective procedure for OSA."[197] In a surgical update published by the American Association of Oral and Maxillofacial Surgeons, Moore affirmed these conclusions: "Jaw advancement surgery is better tolerated and has a far more significant and beneficial effect than most airway soft tissue surgical procedures [for OSA]. Excellent long-term [5-year] results have been documented with favorable effects on quality of life."[238]

The abundance of published data now confirms that those individuals with documented OSA; anatomic findings of minimal tonsillar tissue and minimal redundant pharyngeal soft tissues; and physical findings of recessive jaws will not sufficiently respond to surgical procedures that are less thorough than MMCA. With today's state of knowledge, a treatment philosophy that suggests that an individual with documented OSA must "fail" Phase I soft-tissue reduction surgery before proceeding to Phase II skeletal expansion surgery" is like saying that a patient with a complex tumor defect must first fail a skin graft before undergoing an effective vascularized flap reconstruction.[209] Although an automatic "soft-tissue first" and "step-wise" surgical approach to OSA made sense during the 1980s, it does not make sense for the 21st century. The soft palate is a dynamic tissue organ with the primary function of preventing the reflux of air and liquids into the nasopharynx during speech and swallowing. Unfortunately, partial surgical ablation or resection of the soft palate (i.e., UPPP) may produce dysfunction, such as velopharyngeal insufficiency, stenosis, voice changes, dysphagia, or silent apnea. In addition, immediate postoperative concerns of pain, hemorrhage, and upper airway obstruction must also be considered. For these reasons, a case can be made for treating the most severe and critical site or area of obstruction first. This will frequently mean performing MMCA initially and then following up later with soft-tissue procedures, when indicated. This skeletal approach will enlarge and stabilize the entire velo-orohypopharyngeal upper airway to definitively treat the OSA and frequently to obviate the need for other soft-tissue procedures (e.g., UPPP, tongue reduction, tonsillectomy).

To review, treatment recommendations for OSA should be made in accordance with the patient's specific anatomic, physiologic, and psychosocial factors. OSA is commonly the result of multiple anatomic deformities that are correctable. The concept of a Phase I soft-tissue approach that is followed by Phase II skeletal procedures as a last resort should be discarded in favor of treating the specific anatomic abnormalities that are contributing to the individual's OSA, preferably during a single operation.[104]

Review of Published Studies concerning Maxillomandibular Advancement Surgery

Critical commentary in the earlier medical literature regarding the spectrum of surgical options may leave sleep physicians and others skeptical of the efficacy of any operative procedure for their patients with OSA. With the use of nasal CPAP as the reference for OSA therapy, a standard for a successful outcome has been established; this standard defines an acceptable compliance rate as 4 hours of CPAP per night for 70% of nights. However, this represents only approximately 50% of sleep time involving a normal airway. Li suggested that an equivalent standard for rating a successful surgical outcome is a 50% reduction in the RDI and fewer than 20 events/hour.[200] If we keep this proposed standard for treatment success in mind, then the literature clearly supports an MMA approach to OSA. Clinical studies that were published between 1989 and 2012 and that were carried out to evaluate the effectiveness of MMA as a treatment approach for OSA are reviewed in the remainder of this section.

Waite and colleagues described 23 consecutive patients with OSA documented by PSG (RDI range, 11 events/hour to 104 events/hour) who underwent MMA in addition to septoplasty and inferior turbinate reduction.[381] Twenty-two of 23 (96%) of the study patients were successfully treated. Successful treatment was based on achieving an RDI of less than 20 events/hour or that represented a more than 50% reduction in RDI. Sixty-five percent of the patients (15/23) achieved an RDI of less than 10 events/hour.

*References 3, 17, 24, 29, 55, 56, 59, 62, 82, 83, 109, 123, 131, 141-145, 149, 177, 179, 196, 197, 199, 200, 203, 208, 214, 222, 225, 227, 251, 274, 279, 283, 284, 287, 299, 300-303, 306, 311, 321, 347, 371, 372, 379, 381, 382, 397

Riley and colleagues reported on 40 patients with OSA documented by PSG who underwent maxillomandibular advancement.[302] Thirty-nine of the 40 study patients (97%) were successfully treated. Successful treatment was based on achieving a postoperative RDI of less than 20 events/hour or a more than 50% reduction in RDI and normal or near normal oxygen saturation. A mean presurgical RDI of 67 events/hour was reduced to 9 events/hour.

Riley and colleagues described 306 consecutively treated surgical patients with PSG-documented OSA.[305] A two-phase surgical protocol was used to reconstruct the upper airway. Phase I surgery consisted of UPPP and genioglossus advancement with hyoid myotomy suspension. Patients for whom Phase I surgery was unsuccessful were offered Phase II reconstruction in the form of maxillomandibular advancement. Surgery was considered successful if the postoperative RDI was less than 20 events/hour with normal oxygenation. Ninety-one patients who failed Phase I treatment entered the Phase II protocol. All patients who underwent Phase II treatment (i.e., maxillomandibular advancement) also had perioperative orthodontics. The success of Phase II therapy was 97% (i.e., RDI <20 events/hour with normal oxygenation).

Hochban and colleagues discussed 38 consecutive patients with OSA documented by PSG (RDI >20 events/hour) who underwent MMA (10-mm maxillary advancement); 37 of 38 of the study patients (95%) were successfully treated.[144] Successful treatment was based on achieving a postoperative AHI of less than 10 events/hour. This clinical series included only healthy, non-obese patients with a documented dentofacial skeletal deformity.

Prinsell reported on 50 consecutive patients with PSG-documented OSA (mean AHI, 59 events/hour) who underwent MMA, with or without adjunctive procedures.[283] All 50 patients were successfully treated. Successful treatment was based on the achievement of a postoperative AHI of 5 events/hour or less or a more than 60% reduction in RDI.

Li and colleagues described 175 patients with PSG-documented OSA (mean RDI, 72 events/hour) who underwent MMA.[200] One hundred sixty-six of the 175 patients (95%) were successfully treated. Successful treatment was based on achieving a postoperative RDI of less than 20 events/hour or a more than 50% reduction in RDI. The mean preoperative RDI of 72 events/hour was reduced to a mean postoperative RDI of 7.2 events/hour. Eighty-six of the 175 patients (49%) had undergone ineffective Phase I surgery before MMA. The cure rate for these patients in this study was 97% (83 out of 86). The mean age of the patients in this study who underwent Phase II treatment (i.e., MMA) was 44 years.

Bettega and colleagues completed a prospective study of a consecutive series of individuals (n = 51) with severe OSA (mean AHI, 59 events/hour).[29] All of these patients underwent surgical therapy. The surgery was considered successful if the postoperative AHI was less than 15 events/hour with at least a 50% reduction from presurgical rates. Forty-four of the patients initially underwent Phase I surgery, and the success rate of the Phase I procedures was only 22.7% (10 of 44 patients). Twenty of the 51 patients underwent MMA, including 13 patients for whom Phase I surgery had failed and 7 who underwent MMA as the primary treatment. On average, the AHI decreased from 59 events/hour to 11 events/hour after the MMA procedure. Overall, 15 of the 20 individuals undergoing MMA (75%) were considered to have successful outcomes.

Li and colleagues studied a consecutive series of 12 individuals with OSA that had been documented by PSG (mean RDI, 75 events/hour) and who had undergone MMA.[197] The authors were able to demonstrate a decrease in airway obstruction and collapse after MMA as documented by lateral cephalometric radiographs and by fiber-optic nasopharyngoscopy during passive respiration. Postoperative fiber-optic nasopharyngoscopy with the Müller maneuver specifically documented a decrease in airway collapsibility; an improvement in the retro displacement of the tongue base; and an improvement in lateral wall stability. The mean preoperative RDI was 75 events/hour, which improved by 6 months after surgery to 10.8 events/hour. Ten of the 12 patients who had been treated with MMA (83%) were felt to be cured (RDI <20 events/hour).

Fairburn and colleagues described 20 consecutive patients with PSG-documented OSA (AHI range, 26 events/hour to 134 events/hour) who had undergone MMA with at least 10 mm of mandibular advancement.[82] Eighteen of the 20 study patients (90%) were successfully treated. Successful treatment was based on the achievement of a significant reduction in the AHI. Ten of the 20 study patients (50%) achieved an AHI of less than 10 events/hour. There was a mean improvement of 60 events/hour. In addition, there was a measured enlargement of the upper airway space (in both the lateral and the anteroposterior dimensions) for all patients at all levels.

Vicini and colleagues completed a prospective, randomized, controlled trial to assess the effectiveness of surgery versus ventilation in adults with documented severe OSA (AHI average of >30 events/hour; range, 31 events/hour to 87 events/hour).[376] Fifty consecutive subjects who had severe OSA were enrolled and randomized into a conservative treatment group (i.e., auto-titrating positive air pressure) or a surgical treatment group (i.e., MMA). One year after MMA surgery or continuous auto-titrating positive air pressure treatment, both groups showed a remarkable improvement of mean AHI and ESS levels. The degree of improvement was not statistically different between the two groups. The MMA group (n = 25) had a mean age of 49 years, with a mean BMI of 32.7 kg/m^2 and a mean preoperative AHI of 56.8 events/hour. After MMA surgery, the mean postoperative AHI dropped to 8.1 events/hour ± 7.0. There were no fatal events, no significant bleeding events, and no complications that required a surgical revision procedure. According to a survey questionnaire, the subject's personal perception of the overall surgical experience was highly satisfactory. Twenty-four of the 25 patients stated they could "go through the operation all over again." MMA

proved to be a valuable alternative therapeutic tool in adults with severe OSA, with a success rate equivalent to that of therapeutic ventilation treatment.

Ronchi and colleagues completed a study to evaluate the effectiveness of MMA in patients with PSG-documented OSA.[311] Two groups with different skeletal patterns were studied. Group I (n = 11) had moderate or severe OSA and cephalometrically documented mandibular deficiency (i.e., a sella–nasion–A-point angle of ≤78 degrees or a sella–nasion–B-point angle of <65 degrees and a Class II malocclusion). Group II (n = 11) had moderate or severe OSA without cephalometrically documented maxillomandibular hypoplasia (i.e., a sella–nasion–A-point angle of >80 degrees and a Class I malocclusion). Preoperative and postoperative data collected included AHI; posterior airway space measurement; sella–nasion–A-point and sella–nasion–B-point angles; ESS scores; body mass index; and a subjective standardized questionnaire about facial aesthetics. Results documented that all patients (Groups I and II) achieved increased posterior airway space and the remission of OSA and that both groups were comparable. All patients were satisfied with the functional and aesthetic results achieved. In Group I, AHI decreased from 57.9 events/hour to 7.0 events/hour after surgery. Five patients reported slight improvement and six reported great improvement in their aesthetic results. In Group II, AHI decreased from 50.7 events/hour before surgery to 7.6 events/hour after surgery. Five patients reported slight improvement, five reported no changed, and one reported great improvement in facial appearance. No patients (Group I or II) reported a worsening of the aesthetic appearance. The study confirms that MMA is effective for patients with moderate to severe OSA and even in those who are considered to have cephalometrically normal skeletal and Angle-classified occlusions.

Holty and Guilleminault completed an extensive meta-analysis of the outcomes of MMA surgery. A total of 627 patients from 42 study populations were identified from a review of 914 reports.[149] The mean age was 44.4 years, and 88% of the study subjects were men. The mean postsurgical follow-up period was 5.3 months, and 67% of patients had previously undergone less invasive OSA treatment procedures without success. The MMA surgical success rate was 86%. As a result of the MMA procedures, the following occurred:

1. BMI decreased from 30.4 kg/m^2 to 29.4 kg/m^2.
2. AHI improved from 63.9 events/hour to 9.5 events/hour.
3. Oxygen nadir improved from 71.9% to 87.7%.
4. AI improved from 34.7 events/hour to an average of 1.6 events/hour.
5. Quality of life assessments documented a 72% absolute reduction in depression and irritability.
6. Systolic blood pressure improved from 139 mm Hg to 124 mm Hg.
7. Improvement in rapid eye movement sleep and Stage III or IV sleep was significant.

Fifty-six patients from three specific studies reported the long-term success rates after MMA procedures. With an average follow-up period of 43.7 months, an 89% success rate was documented. Univariant and multivariant predictors of MMA surgical success were younger age; lower preoperative AHI; lower BMI; and greater degree of maxillary advancement accomplished. Older age (>60 years) and higher BMI (>33 kg/m^2) were negative predictors of a successful outcome. However, according to the study results, this does not mean that even those patients with negative predictors cannot experience significant improvement.

Prinsell completed a literature survey and made treatment recommendations regarding both primary and secondary MMA with or without adjunctive procedures for adults with OSA.[44,285] A critical review of all published studies that included six or more cases per series of MMA and other multilevel surgery in adults that also documented preoperative and postoperative AHI was conducted. The AHI data from the case series were tabulated into categories of surgery from which the mean percent reduction of AHI was calculated and used as the primary measure of PSG therapeutic efficacy. The review of published studies indicates a mean percent reduction in AHI as follows:

- An 88.4% reduction of AHI for primary MMA
- An 86.6% reduction of AHI for secondary MMA
- A 79.4% reduction of AHI for primary MMA with combined intrapharyngeal procedures
- A 92.1% reduction of AHI for primary MMA with combined extrapharyngeal procedures
- A 53% reduction of AHI for non-MMA multilevel surgery
- A 31.3% reduction of AHI for UPPP
- An 89.8% reduction of AHI for nasal CPAP

The authors concluded that both primary and secondary MMA are highly therapeutic because they are extrapharyngeal procedures that open the entire velo-orohypopharyngeal airway via skeletal advancement with minimal risk of postoperative airway compromise.

Goodday and Bourque completed a prospective study to evaluate subjective outcomes and the use of CPAP after MMA surgery for the treatment of OSA. A self-administered questionnaire was completed preoperatively and postoperatively by the study patients (n = 16) who underwent MMA for OSA during a 10-year period from 2000 to 2010. The questionnaire included the ESS as well as questions about snoring, witnessed apneas, CPAP use, and overall individual personal satisfaction. Preoperatively, 40% of patients were very sleepy (ESS scores of ≥16), 32% were sleepy (ESS scores of 10 to 16), and 28% were not sleepy (ESS scores of ≤10). After surgery, only one patient (<1%) was very sleepy, 9% were sleepy, and 90% were not sleepy. Surgery was also found to decrease snoring by 83%, witnessed apneas by 94%, and CPAP use by 96% ($P < .001$). The surgery was judged to be worthwhile by 89% of patients,

and 95% of patients said that they would recommend the treatment to others with OSA.

Conclusions

The public health burden that is attributable to sleep disorders is undisputed, and the derangements that result from these disorders are both behavioral and pathophysiologic. The fundamental problem associated with an OSA event is the inability to maintain upper airway patency during sleep, which then results in a reduction (i.e., hypopnea) or a cessation (i.e., apnea) of breathing. The obstruction can occur at any level of the upper airway. It is critical to diagnose the sites of obstruction so that effective treatment can proceed. For the majority of individuals with moderate to severe OSA, all of the sites are at least partially obstructed. All areas of obstruction will likely require improvement to significantly relieve the individual's apnea events. Achieving and maintaining a normal BMI and avoiding medications that negatively affect oropharyngeal muscle tone are also clear objectives. The concept of soft-tissue (intra pharyngeal) surgery being performed first and only later followed by skeletal (jaw advancement) surgery is antiquated. Contemporary thinking aims to tailor treatment to match each patient's set of anatomic deformities.

Clinical studies confirm that MMCA—often in combination with intranasal procedures (septoplasty, inferior turbinate reduction, and nasal floor recontouring) and limited uvulectomy (if indicated)—is relatively safe and highly effective for the treatment of OSA when multiple sites of upper airway narrowing are present. Published studies consistently document that MMCA is the most effective surgical alternative to tracheostomy, with results that are comparative to the therapeutic efficacy of nasal CPAP.

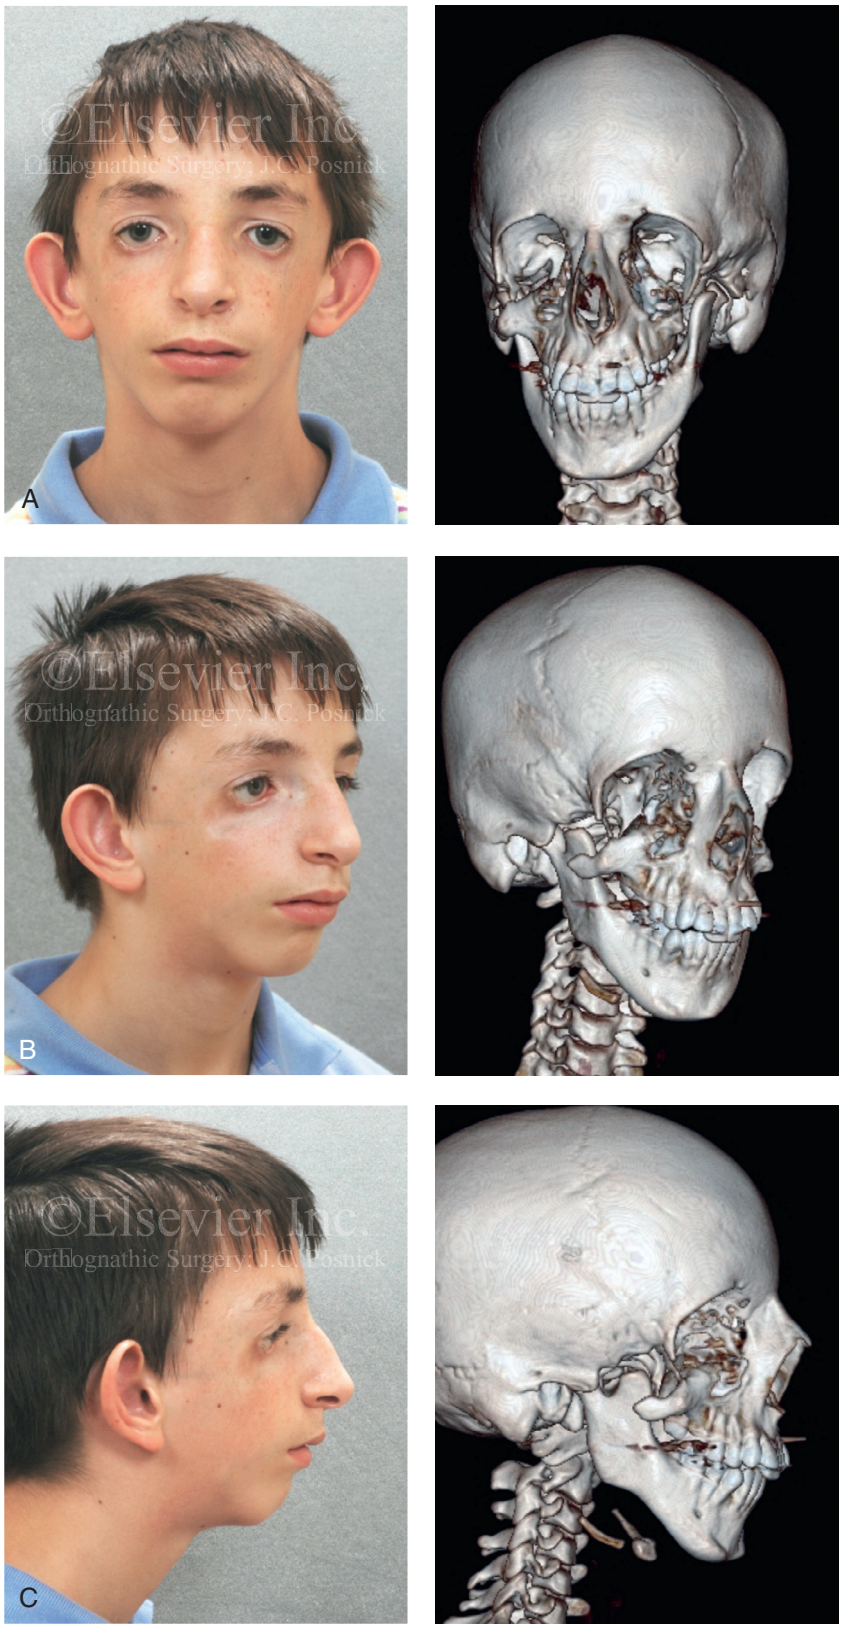
- Conclusions

Treacher Collins syndrome (TCS), which is also known as *mandibulofacial dysostosis,* is an autosomal dominant condition with variable expressivity.* It is generally characterized by bilaterally symmetric abnormalities of the structures within the first and second branchial arches. Early descriptions are attributed to Berry,[10] Treacher Collins,[51] and Franceschetti and Klein.[41] To date, the physical findings of many hundreds of individuals and families with TCS have been published in the world literature.

*References 6, 9, 24, 26-28, 38, 41, 42, 46, 50, 51, 56, 57, 65, 78, 79, 84, 96, 116, 117, 126, 128, 138, 157

The adult patient with fully expressed TCS has a convex horizontally deficient facial profile with a prominent nasal dorsum above a retrusive lower jaw and chin (Fig. 27-1). The eye region is characterized by an antimongoloid slant of the palpebral fissure as a result of colobomata and hypoplasia of the lower lids and the lateral canthi, including the partial absence of the eyelid cilia and inferolateral orbital hypoplasia and dystopia. Tongue-shaped processes of hair frequently extend into the preauricular region. The external ears are absent, malformed, or malposed and hearing is impaired as a result of variable degrees of hypoplasia of the external auditory canals and the ossicles of the middle ears. A characteristic finding is hypoplasia of the malar bones, often with clefting through the arches and limited formation of the residual zygomas, including the glenoid fossa component. The maxilla and mandible bones are also characteristically hypoplastic, with variable effects on the temporomandibular joints (TMJs), the muscles of mastication, and the muscles of facial expression. Interestingly, hypoplasia of the centrally located soft tissues of the face is not seen with TCS. In general, there is an Angle Class II anterior open-bite malocclusion and a steep clockwise-rotated maxillomandibular complex. The posterior facial height is short, and the anterior lower facial height is long. The A-point–to–B-point relationship in profile is consistent with the clockwise rotation of the jaws. The presence of cleft palate (with or without cleft lip and choanal atresia of the nasal cavity) is variable. Dental anomalies are present in 60% of individuals; these include tooth agenesis (33.3%), enamel opacities (20%), and the ectopic eruption of the maxillary first molars (13.3%).

Individuals with TCS have a reduced cranial base angle (i.e., basilar kyphosis). Craniosynostosis is not a feature of TCS, but the neurocranium may have an abnormal shape (i.e., decreased anteroposterior length and diminished bitemporal width) that is evident during childhood and remains through adulthood. [110] The degree of craniofacial malformation present at birth is believed to be relatively stable and non-progressive with age (this is discussed in more detail later in this chapter). TCS should not be



• **Figure 27-1** An 11-year-old boy with fully expressed Treacher Collins syndrome. His eyes are characterized by an antimongoloid slant of the palpebral fissures as a result of colobomata and hypoplasia of the lower lids and the lateral canthi, including the partial absence of the eyelid cilia and inferolateral orbital dystopia. The appearance of the malpositioned adnexal structures is a reflection of both zygomatic–orbital dystopia and hypoplasia of the soft tissues. The maxilla and the mandible are also deficient and malformed. The patient demonstrates a Type IIA mandibular malformation. The external ears are malformed and lack antihelical folds. **A,** Frontal facial and three-dimensional computed tomography scan views. **B,** Oblique facial and three-dimensional computed tomography scan views. **C,** Profile facial and three-dimensional computed tomography scan views.

confused with similar entities such as oculo–auriculo–vertebral dysplasia or Goldenhar syndrome. Distinguishing facial features of patients with TCS often include coloboma of the lower eyelids; the upper eyelids are more likely affected among patients with Goldenhar syndrome.

Inheritance, Genetic Markers, and Testing

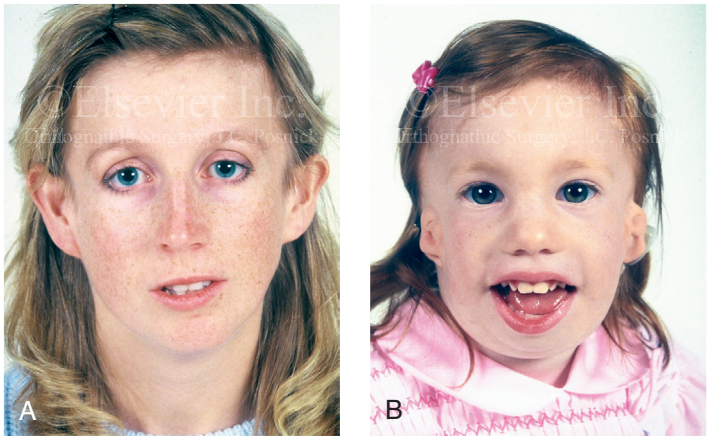
The occurrence of TCS is in the range of 1 in 25,000 to 1 in 50,000 live births. Inheritance is autosomal dominant, and male and female individuals are equally affected.[51] About 60% of probands with TCS have the disorder as the result of a de novo gene mutation. Each child of an individual with TCS has a 50% chance of inheriting the mutation (Fig. 27-2). Teber and colleagues identified TCOF1 mutations in 28 out of 36 (78%) individuals with a clinically unequivocal diagnosis of TCS.[147] The most frequent clinical findings were downward-slanting palpebral fissures, hypoplasia of the zygomatic complex, hypoplasia of the mandible, conductive deafness, any degree of microtia, and atresia of the external ear canal. Although there were interfamilial and intrafamilial variations that ranged from mild to severe, there were no genotype or phenotype correlations. Four clinically unaffected parents were heterozygous for the TCOF1 mutation. The authors concluded that modifying factors are important for phenotypic expression.

Genetic counseling for TCS is the process of providing individuals and families with information about the nature, inheritance, and implications of the syndrome to help them make informed medical and personal decisions. Molecular testing should be considered for any individual who presents with at least two major features or three minor features of TCS.[30,32,34,62,63,72,85,88,89,154,161,165] Until recently, penetrance in TCS was believed to be complete. Marres and colleagues confirmed the absence of clinical and radiographic findings in an individual with a pathogenic TCOF1 mutation. For this reason, testing is acceptable for individuals with any degree of severity of TCS features to confirm or refute the diagnosis.

Prenatal diagnosis for pregnancies that are at increased risk for TCS is possible via the analysis of DNA extracted from fetal cells obtained by amniocentesis; this is usually performed at about 15 to 18 weeks' gestation. Chorionic villus sampling can also be used for diagnosis at about 10 to 12 weeks' gestation. The malformation-causing allele of an affected family member must be identified before prenatal testing can be performed.

Considerations during Infancy and into Early Childhood

At the time of the birth of a child with TCS, concerns will center on the adequacy of the airway, swallowing, feeding, hearing, vision (corneal protection), the presence of cleft palate (with or without cleft lip), any other associated malformations, and the psychosocial well-being of the family.[8,17,27,31,77,94,95,101,103,104,120,160] The airway may be compromised as a result of multiple factors. The first is maxillary hypoplasia, which occurs with a degree of choanal stenosis or atresia with the blockage of the nasal airway. Second, mandibular micrognathia with a retropositioned tongue that at least partially obstructs the oropharyngeal and hypopharyngeal spaces will be present. In addition, tracheomalacia, vocal cord anomalies, or neuromotor involvement may also negatively affect the upper airway. Depending on the severity of the anomalies, a spectrum of upper airway compromise may necessitate, at a minimum, special infant positioning, an extended hospital stay, and pulse oximetry monitoring. Surgical considerations for the management of airway compromise in the infant or young adult may include tongue–lip adhesion, the use of a custom-made oral



• **Figure 27-2** This mother and daughter demonstrate the extent of variation in the expression of Treacher Collins syndrome within a family. The mother was not aware that she carried the Treacher Collins gene until after the birth of her daughter. *From Posnick JC: Treacher Collins syndrome: perspectives in evaluation and treatment,* J Oral Maxillofac Surg *55:1120, 1997.*

appliance, immediate or delayed tracheostomy, or an urgent mandibular advancement procedure.

As a result of any compromise in nasal and oral breathing and associated musculoskeletal malformations, the newborn with TCS may also have difficulty with swallowing and with achieving an adequate lip seal to the extent that urgent gavage-assisted feedings or the placement of a gastrostomy tube may be required to ensure adequate nutrition.

When a cleft of the secondary palate is documented, potential additive effects on the airway before and after repair must be considered. When Nager syndrome is present, the soft palate is both clefted and severely hypoplastic to the extent that the achievement of a functioning palate is not feasible.[65,96] A primary pharyngeal flap—although helpful for velopharyngeal function—is rarely indicated, because further obstruction of the airway would likely result. Evaluation by a *medical geneticist* is indicated to clarify the diagnosis and all presenting anomalies, to discuss family planning issues, and to analyze chromosomal studies.

Within a few days of birth, the results of an examination by an experienced *pediatric otolaryngologist* in combination with formal *audiology testing* will clarify the extent of conductive hearing loss and allow for the early fitting of hearing aids to assist the infant with the acquisition of communication skills and encourage the normal bonding process with the family.

At some point early in life, a complete craniofacial *computed tomography (CT) scanning* from the top of the skull through the cervical spine with three-dimensional reformation will be useful to document the extent of craniofacial skeletal anomalies. Special *focused cuts through the petrous temporal bones* are also required to document external auditory canal and middle and inner ear anatomy. Appropriate craniofacial, maxillofacial, cleft lip and palate, and auricular reconstructive surgeons should also be consulted, as indicated.

An assessment by a *pediatric ophthalmologic* is necessary to determine associated eye anomalies, extraocular muscle function, corneal exposure difficulties, and visual acuity. Ophthalmologic issues may include vision loss (37%), amblyopia (33%), refractive errors (58%), anisometropia (17%), and strabismus (37%). Interestingly, it has been the impression of many clinicians and scientists that the individual with TCS has a tendency toward a short stature, at least early in life, and that above-average intelligence is generally observed.

Dysmorphology with Treacher Collins Syndrome

Cranio–Orbito–Zygomatic Region

In earlier published studies, 14 reproducible cranio-orbito-zygomatic measurements taken from each of 26 standard axial CT scans of individuals with symmetric forms of TCS who had not been operated on were compared with the measurements of age-matched controls.[110] The interorbital measurements (i.e., medial and lateral orbital wall separations) of the patients with TCS were at the mean when compared with their cohort group (i.e., no measurable orbital hypertelorism or hypotelorism), whereas the zygomatic measurements were significantly less than normal, thereby confirming the extent of malar hypoplasia. The congenitally deficient lateral aspect of the orbits in individuals with TCS was confirmed by the greater than normal values measured for globe protrusion and medial orbital wall protrusion in conjunction with diminished lateral orbital wall lengths. These measurements use the lateral orbital rim as a reference point and confirm the limited depth of the lateral orbits as a result of hypoplasia of the lateral orbital rims. The lateral orbital rims are components of the hypoplastic zygomatic complex. The abnormal shape of the anterior cranial vault in patients with TCS was documented as a diminished intercoronal (bitemporal) distance (width) and decreased cephalic length as compared with values for normal age-matched controls. In general, the CT measurements documented in the described study agree with the clinically observed morphology of TCS. The measurements carried out in the zygomatic structures confirmed the extent of hypoplasia of the zygomas for the group as a whole and in each individual patient; they also documented the extent of globe protrusion and decreased upper face width in patients with TCS. It appears as though the bones immediately adjacent to the involved zygomatic complex also experience a degree of hypoplasia or at least distortion.[4,28,39,87,110,113,125,158,159,167,169]

Maxillomandibular Region

In 1975, Roberts and colleagues completed a radiographic cephalometric study of TCS. Serial cephalometric radiographs were available for eight patients who presented with the full range of features that are characteristic of this syndrome.[124] The expected facial convexity in patients with TCS was substantiated by cephalometric measurements. The extent of convexity was attributed to the severity of mandibular retrognathia (i.e., a decreased sella–nasion–B-point angle). Interestingly, the horizontal projection of the maxilla to the cranial base (i.e., the sella–nasion–A-point angle) remained within normal limits in the patients that were measured. Over time and with growth, the facial convexity remained relatively constant, thus confirming that the facial profile morphology of the infant with TCS was remarkably similar to that of the adult. Anterior facial heights were measured as "upper facial height" (i.e., the nasion to the anterior nasal spine) and "total facial height" (i.e., the nasion to the menton). The upper facial height was found to be relatively normal, whereas the total facial height was often excessive. This is the result of a combination of anterior open-bite malocclusion, mandibular retrognathism, and chin dysplasia characterized by increased vertical length and horizontal retrusion. The angle between the sella–nasion plane and the mandibular plane was obtuse,

which confirmed the steepness of the clockwise rotation of the mandibular plane. The angle between the sella–nasion plane and the palatal plane was also obtuse, thus confirming the steepness of the clockwise rotation of the maxillary plane. The posterior facial height was markedly shorter for patients with TCS, with values in five of the eight patients found to be a minimum of four standard deviations less than those of the normal cohort.

The effective horizontal length of the mandible was markedly reduced, with values in most of the patients falling below four standard deviations as compared with those in the normal cohort. The decreased mandible size was evident in both the ramus height and the body length. The gonial angle was confirmed to be obtuse, with values of two standard deviations from the mean as compared with control values. The extent of antigonial notching was also documented in patients with TCS and was found to be similar to that observed among patients with condylar arrest early during their lives (e.g., as a result of juvenile rheumatoid arthritis or TMJ trauma at a young age). The steepness of the clockwise rotation of the maxillary and mandibular planes combined with the anterior and posterior vertical height disproportions and severe horizontal deficiency of the mandible is also indirectly seen in the A-point–to–B-point discrepancy. All of these morphologic findings explain the observed facial dysmorphology.[4, 39,49,78,79,87]

Facial Soft Tissues

Soft-tissue anomalies in individuals with TCS are manifested primarily in four clinical regions: the external ears; the eyelid–adnexal structures; the preauricular–cheek skin; and the temporal fossa (e.g., temporalis muscle hypoplasia).[10,11,22,35,36,64,76,86,132,133,143,148,156] The extent of deficiency within the soft-tissue envelope is variable and, to large extent, reflective of the skeletal involvement. Each patient is unique and must be evaluated individually. The extent of soft-tissue anomalies continues to represent the most difficult obstacle to a favorable reconstruction.

External Auditory Canal, Middle and Inner Ear Structures, and Audiologic Findings

Relatively symmetric (i.e., from side to side) outer and middle ear malformations are characteristic of TCS. Middle-ear abnormalities (e.g., hypoplastic or absent cavities and ossicles) are an almost universal finding.[18,55,58,66,118] The majority of patients have a unilateral or bilateral moderate or greater conductive hearing loss, with a flat or reverse sloping configuration on the audiogram. Most of the hearing loss in these patients is attributable to middle-ear malformations. In 1993, Pron and colleagues reported the results of a detailed CT radiologic and audiologic investigation of a large series of pediatric patients with TCS.[118] The objectives of the study were 1) to determine the degree and symmetry of the external auditory canal and middle-ear abnormalities and evaluate hearing loss; and 2) to explore the relationship between hearing loss and external auditory canal and middle-ear abnormalities in patients with TCS. Data were available from 29 children who had not yet undergone any ear interventions and who had undergone audiometric testing and focused standardized petrous temporal bone CT scans. A review of the CT scans allowed for the evaluation of the external ear canal and the middle-ear anatomy. The majority of patients (88%) had largely symmetric external auditory canal abnormalities that were either stenotic (31%), atretic (54%), or normal (15%). Middle-ear cavity ossicular deformities were generally symmetric (96%), and cavities were either hypoplastic (85%) or missing (4%). Cavities that were hypoplastic were also deformed and assumed a rectangular rather than an oval shape. Ossicle deformities were generally completely symmetric and consisted largely of hypoplastic (46%) or missing (46%) ossicles. Ossicles (both the malleus and the incus) that were hypoplastic also tended to be ankylosed (82%) to either the lateral or medial wall of the tympanic recess. The structures of the external auditory canal and the middle ear are generally related. Increasing degrees of external ear canal malformations (i.e., normal, stenotic, or atretic) are directly associated with ossicle and cavity malformations. Of the patients with atretic canals, 67% had missing ossicles, and 33% had small or ankylosed ossicles. No abnormalities were noted in the inner-ear structures (i.e., cochlea, vestibule, canals, and internal auditory meatus) in the patients with TCS who were studied. According to the study by Pron and colleagues, hearing loss for the patient with TCS ranges from mild to severe (average, 58 dB of hearing loss).[118] The majority of individuals (96%) have a moderate or greater degree of hearing loss.

Relationships exist between the external auditory canal, the middle-ear ossicles, and the degree and configuration of hearing loss.[18,55,58,66,118] There is an association between the degree of external ear canal malformation and the degree of hearing loss in patients with TCS. In addition, hypoplastic, ankylosed, and missing ossicles appear to be associated with increasing levels of hearing loss; on average, the hearing loss is 52 dB, 56 dB, and 60 dB of hearing loss, respectively.

Facial Growth Potential with Treacher Collins Syndrome

The degree of malformation present at the time of birth in a newborn with TCS is believed to be relatively stable and non-progressive with age (Figs. 27-3 through 27-6).[53,102,109,114,115,124] Roberts and associates reviewed serial cephalometric radiographs from individuals who were known to have TCS.[124] They documented the stability of the mandible, which continued to grow but not to catch up. Through independent research, Garner reported findings of the cephalometric analysis of three patients of varied ages who were confirmed to have TCS.[49] He also

documented the relative stability of the anomalies without the progression of deformity at various ages.

To date, no convincing evidence demonstrates a clinically significant worsening of the TCS dysmorphology with facial growth. Early surgical interventions with mandibular osteotomies involving the use of either osteodistraction or standard orthognathic techniques are believed to adversely affect growth, thereby necessitating revision osteotomies at maturity. For this reason, waiting until the majority of jaw growth is complete before reconstructing the maxillomandibular components is recommended, if feasible. In any case, early mandibular surgery should not be expected to prevent the need for definitive maxillofacial reconstruction at maturity.

Classification of Temporomandibular Joint and Mandibular Malformation

The extent of TMJ–mandibular malformation in patients with TCS will influence the timing and techniques of reconstruction.[69,137] A lack of clinically relevant definitions of the presenting glenoid fossa–condyle–ascending ramus malformations has resulted in confusion and miscommunication. Kaban and colleagues revised and clarified the previously described Pruzansky classification system for the degree of TMJ–mandibular malformation observed in patients with hemifacial microsomia.[69,119] This classification is also useful to define the presenting anomalies and then to direct reconstruction in the patient with TCS (Fig. 27-7).

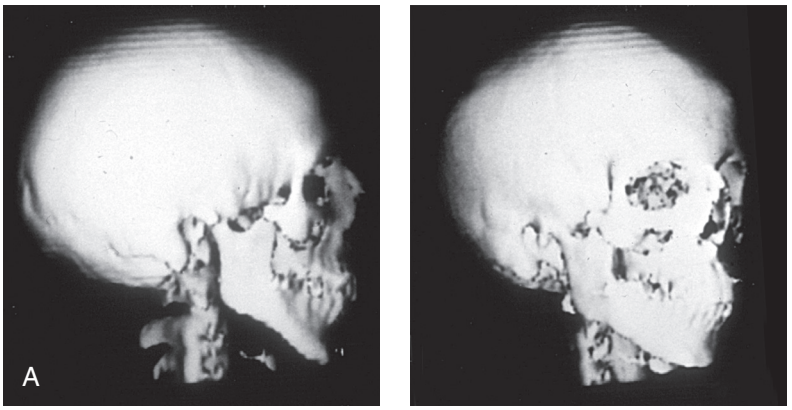
A Type I TMJ–mandibular malformation involves minimal hypoplasia of the glenoid fossa and the condyle–ascending ramus on each side. All of the skeletal components are present (see Fig 27-7, *A*). Mandibular retrognathia and a mild anterior open bite are likely to be present, but TMJ function is essentially normal. The muscles of mastication are intact, and the condyle and the glenoid fossa are also fully intact. There is no need or advantage to constructing a neo-condyle or neo-glenoid fossa.

A Type IIA TMJ–mandible malformation involves a moderate degree of glenoid fossa and condyle–ascending

ramus hypoplasia (see Fig. 27-7, *B, C,* and *D*). The anatomic location of each joint is anterior and medial, but TMJ function remains satisfactory. One or more of the paired muscles of mastication are likely to be hypoplastic. By definition, in Type IIA malformations, the condyle and the glenoid fossa have function that is at a level deemed better than could reliably be achieved through TMJ replacement. Even in patients with more severe Type IIA malformations, when applying superior and posterior pressure to the chin, the condyles can be seated into a consistent location against the skull base–glenoid fossa. By completing ramus osteotomies, the proximal segments can be positioned into a stable location against the skull base, and the distal mandible can then be reoriented into the preferred location. This will avoid the need to construct neo-condyles (e.g., costochondral grafts). Coronoidectomies may be required to accommodate the short condyles.

The Type IIB TMJ–mandibular malformation involves severe hypoplasia of the condyles. The mandible is without a stable centric relation. The glenoid fossa may be hypoplastic, but they are deemed functional. The hypoplastic condyles do not consistently seat in the glenoid fossa, and the mandible functions within a limited range of motion. The extent of mandibular retrognathia and anterior open bite is marked. With Type IIB TMJ–mandibular malformations, the rudimentary condyles are deemed too far medially and anteriorly displaced to be useful. The construction of a neo-condyle ascending ramus with the use of a bone graft is required (see discussion to follow). Coronoidectomies and recontouring of the surgically advanced mandible may be required. Fortunately, this pattern of malformation occurs in only a small percentage of patients with TCS.

The Type III glenoid fossa–mandibular malformation involves deficiency to the extent that no posterior stop of the lower jaw against the cranial base is possible (see Fig. 27-7, *E*). The condyles and the ascending rami are not present. The disc, the TMJ capsule, and the glenoid fossa on each side are also not developed. Severe mandibular dysmorphology is present, including horizontal



• **Figure 27-7** Kaban and colleagues described a classification system to define the degree of temporomandibular joint–mandibular malformation observed in patients with hemifacial microsomia. By definition, a Type IIB condylar deficiency will require the construction of a neo-condyle. The Type III malformation will also require neo-glenoid fossa construction. The same classification system is used for Treacher Collins syndrome. Craniofacial computed tomography (CT) scans demonstrate the classification system. **A,** CT scan views of a Type I mandibular malformation. **B, C,** and **D,** CT scan views of a Type IIA mandibular malformation.

retrognathia and decreased posterior ramus height. A tracheostomy is generally required shortly after birth to manage the airway. Eventual construction of both a neo-glenoid fossa and a neo-condyle ascending ramus will be required on each side. Reconstruction with bone grafts (e.g., cranial grafts for the zygomatic complex and either costochondral or a vascularized fibula flap for the mandible) will be required (see discussion to follow).

Staging of Skeletal Reconstruction: Timing and Techniques

The reconstruction and rehabilitation of the Treacher Collins malformation must address unique and specific components of the anomalies, including the following: 1) the zygomatic and orbital region; 2) the maxillomandibular region; 3) the nasal region; 4) the soft-tissue envelope; 5) the external ears; 6) the external auditory canals; and 7) the middle-ear structures (Figs. 27-8 through 27-10).*

Zygomatic and Orbital Reconstruction

In previously published studies, we have documented the efficacy of reconstructing the malar and orbital deficiencies for moderate to severe forms of TCS with the use of full-thickness calvarial bone grafts that have been contoured three-dimensionally to form a new zygomatic complex (see Figs. 27-8 and 27-9 through 27-13).[113] The neo-zygoma is then inset and stabilized with microplate and screw fixation. Exposure for the reconstruction is provided by a coronal scalp incision without the need for additional periorbital incisions. Orbital floor defects are reconstructed with fixed split-thickness autogenous cranial bone. Cranial vault donor sites are repaired either with autogenous split cranial grafts or artificial material. For non-autogenous reconstruction of the small skull donor sites, we prefer the use of a titanium mesh base fixed to the adjacent skull. The mesh is then filled in with a bone substitute. Lateral canthopexies are completed through the coronal scalp incision and secured to each new lateral orbital rim. In our study, computed tomography scanning that was performed before surgery and immediately afterward demonstrated significant increases in lateral orbital wall length (depth), lateral orbital (rim) width, interzygomatic arch width, and zygomatic arch length for patients with TCS. The late (i.e., ≥1 year) postoperative scans document that these changes were maintained. No complications occurred during surgery, and repaired skull donor sites healed without clinical defect. Zygomatic and orbital morphologic improvement was achieved in all patients, with follow-up intervals ranging from 24 to 50 months (mean, 35 months) at the close of the study. Unfortunately, over time, I have observed that partial resorption of the zygomatic complex graft occurs in some patients.

*References 1-3, 5, 16, 21, 25, 81, 97-100, 105-107, 109, 110, 112, 114, 115, 121, 122, 127, 153, 151

We believe that reconstructing the malar and orbital deficiencies before the patient is 7 years old is not advisable unless severe corneal exposure problems occur and skeletal deficiency is believed to be the cause. By this age, the cranio–orbito–zygomatic bony maturation is nearly complete. Therefore, adult-sized cheekbones may be constructed and placed with limited concern about how further growth will effect the initial result. In addition, skull donor-site reconstruction is simpler than it is at a younger age, because the presence of bicortical cranial bone in those who are more than 7 years old allows for the splitting of adjacent bone to assist with reconstruction (see Figs. 27-11 and 27-12).

Other surgeons have recommended various methods and time frames for the zygomatic and orbital deformities associated with TCS.[20,45,60,113,125,149,150,152,167,169] We believe that the construction of the complete zygomatic complex from full-thickness autogenous cranial bone maintains volume and shape better than onlay grafts, which have been universally disappointing. Over time, onlay autogenesis bone grafts that have been placed in the craniofacial region (e.g., supraorbital ridge, zygoma, anterior maxilla, angle of mandible, chin) from all tried donor sites (e.g., skull, hip, rib) have demonstrated significant and unpredictable resorption. Furthermore, no commensurate growth (i.e., volume expansion) of the graft with the underlying bone (e.g., zygoma) should be expected. The belief that "even if the graft partially resorbs, at least something has been gained" should be abandoned; surface irregularities routinely result, which further detract from the baseline malformation.

Maxillomandibular Reconstruction

A primary consideration for the timing and technique of jaw reconstruction is to clarify any special airway needs. This will influence whether or not first-stage early mandibular reconstruction is necessary prior to growth maturity. The second consideration is to define the extent of TMJ–mandibular malformation. With Type I and IIA malformations, there is no need for glenoid fossa or condyle construction. In patients with these conditions, adequate TMJ anatomy is present so that mandibular reconstruction can be achieved through ramus osteotomies (e.g., sagittal split, inverted L, distraction [DO]) with the preservation of the working TMJ.

The basic dysmorphologies of the maxillomandibular complex that require reconstruction in patients with TCS are as follows: 1) altered facial heights (increased anterior lower facial height and decreased posterior facial height); 2) horizontal jaw deficiency (primarily in the mandible but also in the maxilla); and 3) chin dysplasia (increased vertical length and horizontal retrusion).[29,43,44,54,61,70,150,152,168] These malformations result in an excessive clockwise rotation of the maxillomandibular complex and an unfavorable A-point–to–B-point relationship when viewed in profile. In general, there is an Angle class II anterior open-bite malocclusion. Interestingly, some individuals will present with

She has severe zygomatic complex and orbital deficiency as well as a Type IIA condylar malformation. **B,** Illustration of the location of the full-thickness cranial bone graft donor site for zygomatic complex reconstruction. The zygomatic complex graft is also shown inset at the recipient site. **C,** Illustrations of a maxillofacial complex seen in a teenager with Treacher Collins syndrome (Type IIA mandibular malformation). The cheekbone orbital reconstruction has previously been completed. The proposed maxillary, mandibular, and chin osteotomies are marked out and then completed. Counterclockwise rotation of the maxillomandibular complex is demonstrated as part of the reconstruction.

• **Figure 27-9** Additional images of the patient from Fig. 27-8 showing the stigmata of Treacher Collins syndrome. At the age of 17 years, the patient was referred to this surgeon and agreed to a staged reconstruction that included three operations. The initial preoperative orthodontic treatment included the extraction of mandibular first premolars with the retraction of the anterior dentition to remove compensations. Orthognathic surgery included a Le Fort I osteotomy (counterclockwise rotation and anterior maxillary intrusion); bilateral sagittal split ramus osteotomies (advancement and counterclockwise rotation); and an osseous genioplasty (vertical reduction and advancement). During a second operation, the patient underwent zygomatic complex reconstruction with fixed full-thickness autogenous cranial bone grafts as described in this chapter and as illustrated in Fig. 27-8. This was followed a third operation: septorhinoplasty (open approach) to in-fracture the nasal bones, reduce the dorsal hump (bone and cartilage), and reshape the tip, including septal (caudal strut) grafting (see Chapter 38). **A,** Right profile views before and after reconstruction. **B,** Left profile views before and after reconstruction.

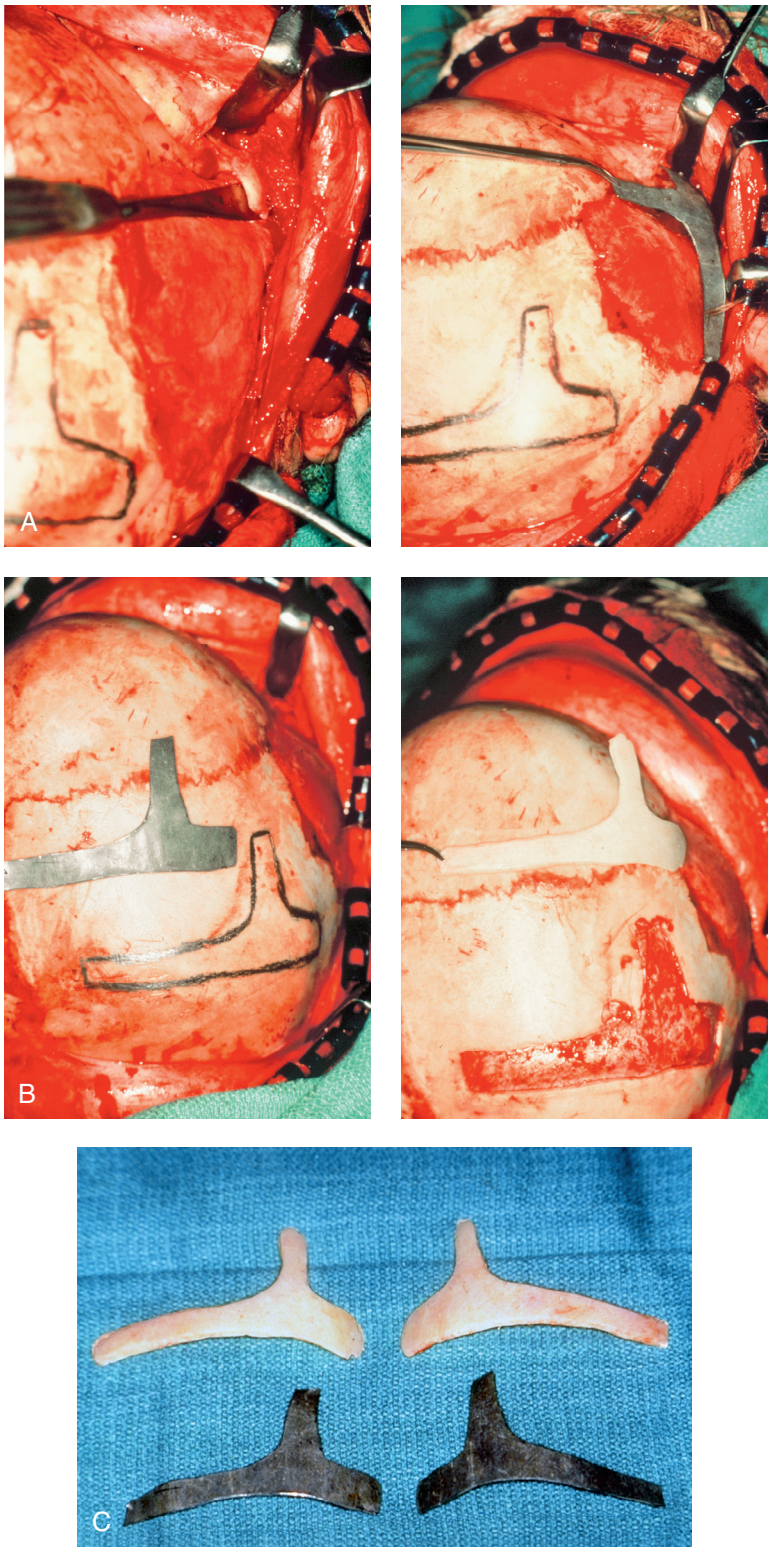
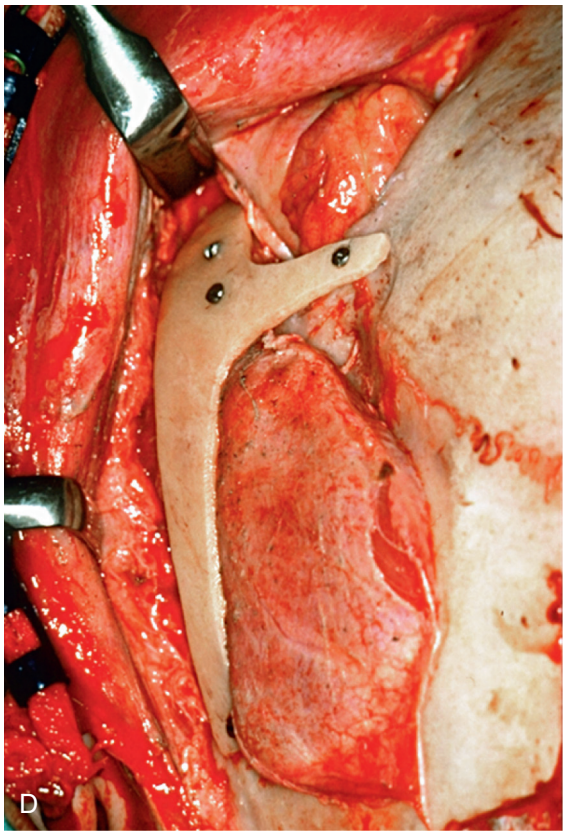
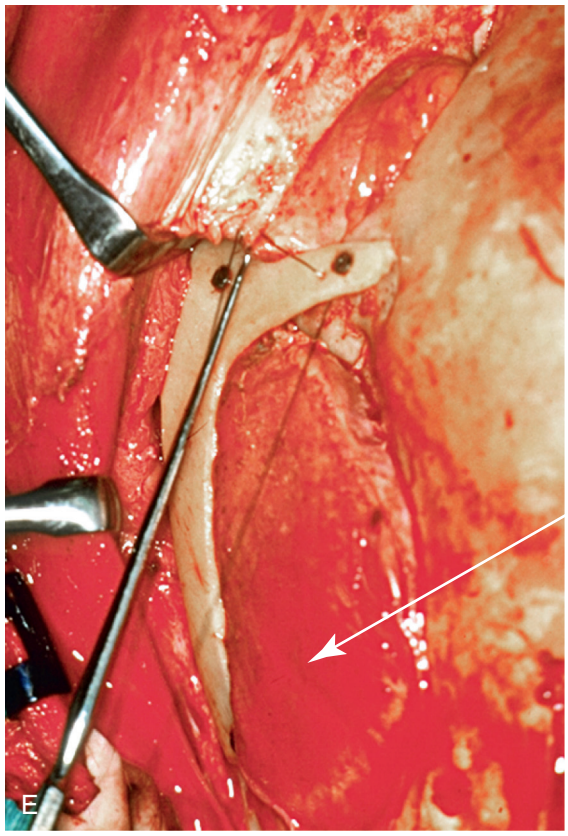
either a Class I or Class III relationship. These aspects must be addressed with the incorporation of counterclockwise rotation of the maxillomandibular complex to increase the posterior airway space, to correct the malocclusion, and to restore facial balance.

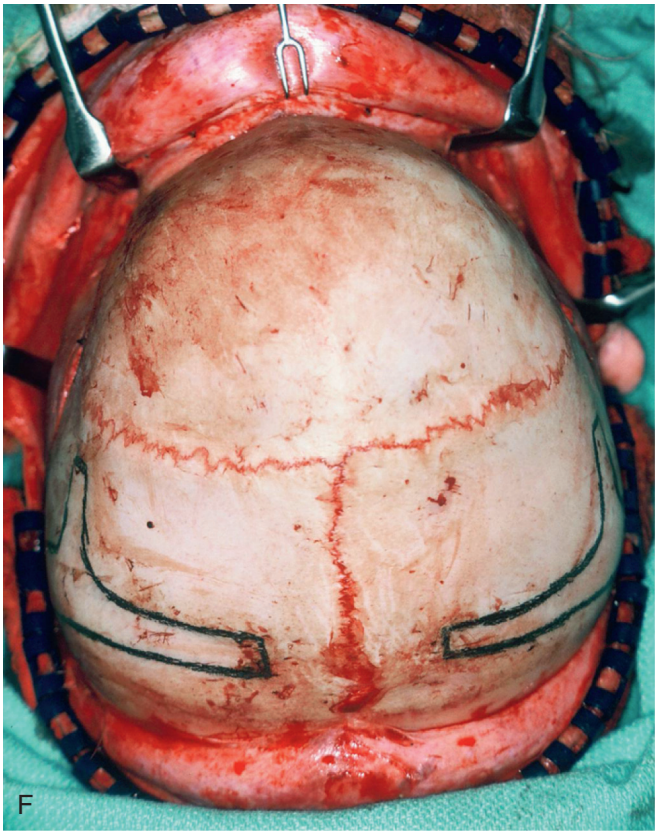
The most favorable aesthetic results are generally achieved in patients who undergo definitive reconstructive jaw surgery only after early maxillofacial skeletal maturity (i.e., after the age of 13 to 15 years) and when these procedures are carried out in combination with effective definitive orthodontic treatment during the permanent dentition (see Figs. 27-8 through 27-10). Mandibular and possibly maxillary premolar extractions are often required to orthodontically unravel dental root crowding, to normalize the

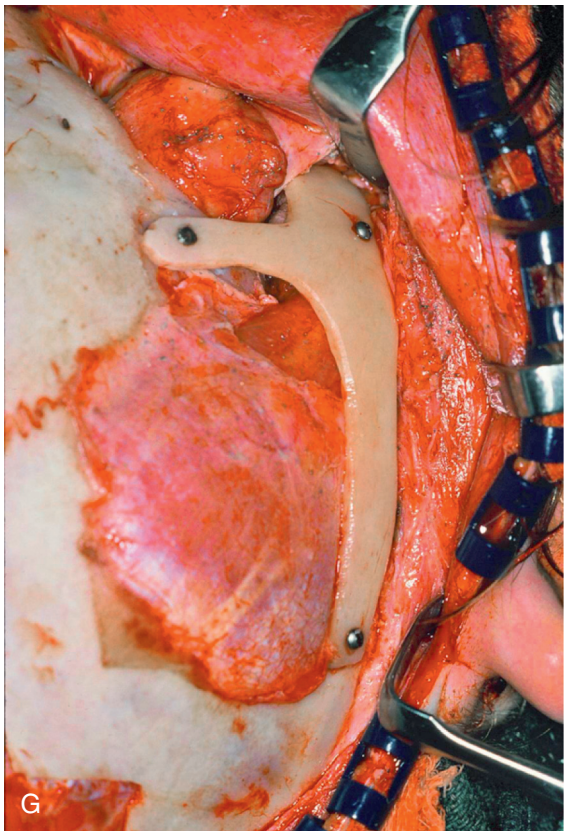


• **Figure 27-12** Intraoperative views demonstrate the technique for zygomatico–orbital reconstruction in a 5-year-old child as it would be carried out for a patient with Treacher Collins syndrome. Working through a coronal (scalp) incision, the rudimentary zygomatic and orbital structures are exposed. Full-thickness cranial bone grafts are harvested, and each zygoma is crafted from such a graft. Each zygoma graft is inset and stabilized with microplates and screws. The orbital defects are reconstructed with cranial bone graft, and the orbital rims are reshaped with a rotary drill. Lateral canthopexies are completed through the coronal scalp incision and fixed to the new frontozygomatic suture regions. **A,** A view of the dissected rudimentary zygomatic remnant; the periosteal elevation is deep to the remnant. A template of the proposed zygomatic complex has been made. **B,** The template is taken to the mid-skull region, and its outline is marked out for craniotomy. The location for graft harvesting is posterior to the coronal suture, lateral to the sagittal suture, and anterior to the lambdoid suture. Through a craniotomy, the full-thickness cranial bone graft is harvested for zygomatic complex reconstruction. The exact same procedure is completed on the contralateral side. **C,** The two full-thickness cranial bone grafts are then crafted. The two templates and the two full-thickness crafted cranial bone graft–zygomatic complexes are shown.









• **Figure 27-12, cont'd** **D,** The full-thickness cranial bone graft is fixed in place with microscrews. **E,** The lateral canthus is identified through the coronal incision and a 28-gauge stainless steel wire is passed through. In the patient shown here, the temporalis muscle has minimal hypoplasia. Thus, minimal temporal hallowing is expected after zygomatic reconstruction. The lateral canthus is pexed to the new frontozygomatic region. **F,** The locations for graft harvesting are outlined. **G,** The right side cranial graft is shown in place. *A,B, From Posnick JC, Goldstein JA, Waitzman A: Surgical correction of Treacher Collins malar deficiency: Quantitative CT scan analysis of long–term results.* Plast Reconstr Surg *92:12, 1993.*

inclination of the anterior teeth, and to fully decompensate the occlusion in preparation for the effective aesthetic and airway repositioning of the jaws (see Fig. 27-7, *A, B, C,* and *D*). The surgical technique involves sagittal ramus osteotomies of the mandible in combination with a Le Fort I (maxillary) osteotomy and an oblique osteotomy of the chin. The incorporation of counterclockwise rotation of the maxillomandibular complex is generally required to successfully accomplish certain objectives. Any intranasal airway obstructions are simultaneously managed (e.g., septoplasty, inferior turbinate reduction, recontouring of the nasal floor, widening of the aperture).

Type IIB mandibular malformations will require surgical construction of the congenitally missing condyle. Osteotomies alone—with the immediate repositioning or gradual DO of skeletal segments—will not be adequate. For the Type IIB malformation, despite inherent limitations, mandibular reconstruction with a costochondral graft remains the preferred alternative when feasible (i.e. this will avoid the need to harvest fibula composite flaps).

The incorporation of the counterclockwise rotation of the entire maxillomandibular complex will also be required to achieve facial balance and an adequate airway. Effective reconstruction can only be predictably carried out with neo-condylar construction followed by maxillary and mandibular osteotomies at or near skeletal maturity. Intranasal procedures to open the airway (i.e., septoplasty, inferior turbinate reduction, recontouring of the nasal floor and walls) are also carried out at the time of definitive jaw reconstruction.

The Type III TMJ–mandibular malformation will require surgical construction of the congenitally missing glenoid fossa and condyle on each side (see Fig. 27-7, *E*). Construction of the neo-glenoid fossa is required and best carried out as part of the zygomatic and orbital reconstruction (see the discussion of zygomatic–orbital reconstruction earlier in this chapter). For the Type III condyle-ascending ramus malformation, construction of a neo-condyle on each side is also required. Mandibular osteotomies alone, with the immediate repositioning or gradual distraction of skeletal segments, will not be adequate. Despite limitations, neo-condylar construction with a costochondral graft remains the preferred alternative when feasible. Occasionally the combined extent of the deficiency of the skeleton and the soft tissues will require the microvascular transfer of a crafted fibula composite flap for each side (i.e., bone and soft tissue). The advantages of a vascularized fibular composite flap are obvious but the donor site morbidity (i.e., need for bilateral lower extremity harvesting) and recipient site requirements (e.g., need for bilateral neck microvascular anastomosis) are significant. In either case, at operation, the distal mandible is repositioned anteriorly to the preferred position of the maxilla. This is assisted by a prefabricated interocclusal acrylic splint, with the distal mandible secured by intermaxillary fixation. The proximal mandible on each side is then constructed with an autogenous costochondral graft or a fibula composite microvascular flap. Contouring of the native mandible with a rotary drill before placing the rib or fibula graft on the lateral side of or adjacent to the edge of the distal mandible is generally required to avoid lateral flaring. Fixation of the graft to the native distal mandible is done with an extended titanium plate from the graft forward along the inferior border of the body of the distal mandible on each side. Graft placement and fixation are generally carried out through an extraoral neck incision. The limited use of intraoral incisions in the ramus regions during this procedure is preferred to minimize the incidence of infection and wound breakdown with subsequent graft loss or TMJ ankylosis.

Indications for First-Stage Mandibular Reconstruction in the Newborn

TCS is a clefting syndrome that involves both sides of the face (i.e., the first and second branchial arches) in which upper airway anomalies occur with both regularity and variation. Hypoplasia of the mandible is one of the constant but variable components of the syndrome.* Individuals with TCS are known to be at risk for sleep apnea, which has been reported to occur in more than 25% of affected individuals. For those with OSA who are tracheostomy dependent, an alternative method of treatment may include the sagittal advancement of the mandible to bring the tongue forward, to create space in the oral cavity, and to open up the retromandibular airway. DO techniques to gradually advance and then hold the mandibular segments until consolidation occurs have been used to improve the airway for almost two decades.* The use of this technique has been reported by several authors as an effective method of decannulating otherwise tracheostomy-dependent individuals with TCS. The implications of this early mandibular advancement approach for long-term airway success and as a definitive jaw reconstruction option for patients with TCS have undergone little critical analysis.[37]

Anderson and colleagues reported the long-term results of mandibular lengthening with a DO approach that was carried out during the patient's childhood for the management of airway obstruction in an individual with TCS.[2] They documented that the airway improved in a 6-year-old patient with TCS after DO of the mandible to the extent that decannulation and the early resolution of airway obstruction were achieved. They showed that the minimum cross-sectional airway in this patient increased during the period of distraction but did not reach age-adjusted normal values. Subsequent serial scans over 10 progressive years of growth demonstrated that the minimal cross-sectional airway did not increase further. Specifically, measurements of the cross-sectional area that were taken at a fixed point of the upper airway (i.e., the base of the C2 vertebral body) demonstrated no increase in the cross-sectional area during growth. The published longitudinal case study from these authors demonstrates a failure of a sustained satisfactory cross-sectional area of the upper airway with chronologic age. They also used three-dimensional CT scans to document that mandibular growth continued in the same dysmorphic TCS pattern as it had before the distraction intervention. This resulted in an abnormally steep (clockwise rotated) mandibular plane angle. The combination of an increasingly steep mandibular plane angle and the failure of the distraction procedure to produce long-term positive horizontal projection was believed to have created the skeletal basis for ongoing upper airway obstruction. The authors conclude that a mandibular DO procedure carried out in a child with TCS who is experiencing OSA maybe useful for opening the retromandibular airway. However, the initial improvement in the upper airway did not continue during chronologic growth. The clinical consequences were the reemergence of the symptoms of OSA that required further treatment (i.e., continuous positive pressure airway mask at night or tracheostomy). It is also known that a mandibular

*References 17, 21, 47, 48, 53, 59, 61, 67, 70, 71, 90-93, 131, 134, 136, 139, 141, 142, 160, 166

lengthening procedure carried out during early childhood will have other detrimental effects, including injury to the developing teeth; deformational growth of the mandible; facial soft-tissue scarring; injury to the inferior alveolar nerve; a significant incidence of TMJ ankylosis (both bony and fibrous); perioperative cardiovascular and respiratory complications in some patients; expense to the family and medical health care system; and the need for definitive jaw reconstruction at maturity.[7] Despite almost two decades of accumulated worldwide experience, the role of mandibular DO in the treatment protocol for infants and children with TCS remains to be determined through long-term outcome studies. In the absence of sound data, the use of mandibular osteotomies and lengthening procedures—by whatever means—during infancy and childhood should be used cautiously and selectively.

Indications for First-Stage Mandibular Reconstruction during the Mixed Dentition

When a first-stage mandibular reconstruction during the mixed dentition for the Type IIB condylar malformation is felt to be indicated, it is preferably carried out after the child is 7 to 10 years old and only after the eruption of the mandibular permanent first molars.[105-110,112,114,115] Unfortunately, a first-stage early mandibular reconstruction will not provide a long-term resolution of the mandibular and other maxillofacial deformities.* Problems with costochondral graft overgrowth, undergrowth, and asymmetrical growth as well as with infection and TMJ ankylosis continue to plague the reconstructive surgeon (see Chapter 26). The final orthognathic correction of the upper jaw, the lower jaw, and the chin region will be required later, after early skeletal maturity (i.e., after 13 to 15 years of age).

The rationale for postponing the correction of the maxillomandibular deformity until the time of early skeletal maturity (i.e., 13 to 15 years of age) is the same as that for patients with standard dentofacial deformities, for those with other associated syndromes, and for those with a cleft lip and palate jaw deformity. The reasons that mandibular surgery during the mixed dentition is generally not preferred include the following: 1) to avoid injury to the developing permanent dentition and the inferior alveolar nerves[7,164]; 2) to avoid soft-tissue (cutaneous) scarring; 3) to limit perioperative airway and infection complications; 4) to limit the patient's negative psychosocial memories; and (5) to avoid any iatrogenic deformity of the TMJs and the mandible that may add difficulty to the achievement of a long-term favorable reconstruction.

In addition, safe and effective osteotomies in the malformed upper jaw and chin are not carried out during childhood as a result of the position of the developing teeth and the expected induced growth restrictions that would occur. The literature now confirms a lack of continued horizontal maxillary growth after early Le Fort I osteotomy. In addition, the favorable surgical placement of the jaws during the mixed dentition to ensure long-term functional occlusion and enhanced aesthetics is not realistic.

In individuals with TCS, a Le Fort I osteotomy will be required to correct vertical, horizontal, and transverse maxillary deformities. The maxillomandibular complex invariably benefits from counterclockwise rotation for the correction of pitch orientation. Intrusion of the anterior maxilla is generally needed to establish a more normal upper-lip–to–tooth relationship during smile and in repose. The posterior maxillary height may require lengthening, but more frequently it can remain close to a neutral position. The planned maxillary plane change (i.e., pitch orientation) is carried out to achieve appropriate counterclockwise rotation of the mandible and the chin. The objectives are 1) to normalize the anterior facial height; 2) to open the upper airway; and 3) to establish an aesthetically improved A-point–to–B-point relationship when the patient is viewed in profile. In 1993, Rosen documented the long-term stability of the counterclockwise rotation of the lower jaw when this is required to improve function and enhance the facial aesthetics in patients with mandibular micrognathia. Others have carried out similar clinical studies that have confirmed the long-term skeletal stability of mandibular counterclockwise rotation as part of an orthognathic correction.[127,168]

For the Type I and IIA mandibular malformations, bilateral intraoral sagittal split osteotomies are generally the preferred ramus procedures, because they allow for effective horizontal advancement, counterclockwise rotation of the mandible (without the need to actually lengthen the posterior facial height); and sufficient bone contact across each osteotomy site (see Fig. 27-8, *C*). Stabilization at each mandibular osteotomy site is accomplished with titanium plates and screws as needed. Interposed (e.g., autogenous iliac) corticocancellous bone graft is used when required.

For the Type IIB and Type III rib or fibula graft-constructed mandible that was created earlier during the patient's life, splitting in the ramus region at the time of definitive reconstruction is preferred when feasible. The degree of bone contact across the osteotomy site after the advancement of the distal mandible is generally limited in these circumstances. The need for an interpositioned corticocancellous bone graft (e.g., autogenous iliac) should be anticipated (see Chapter 28).

For most patients with TCS, DO osteogenesis techniques have failed to demonstrate lower morbidity or improved soft-tissue response as compared with standard osteotomies.* Data have indicated significant relapse during the consolidation phase of DO techniques and no ongoing jaw growth when the procedure is carried out during childhood. Kaban and colleagues and others continue to refine the application of curvilinear DO for the correction of the

complex mandibular deformities of severe forms of TCS.[69] Despite their best efforts when using DO techniques, reliable three-dimensional vector control to achieve preferred proportions and symmetry of the osteotomized skeletal segments remains a work in progress. For these reasons, until DO technology and its clinical applications improve, we prefer the standard orthognathic correction of the maxillomandibular imbalance in patients with TCS when feasible.

Nasal Reconstruction

The bridge of the nose in the adult with TCS often has mild to moderate increased width, and a mid-dorsal hump is always present. The length of the nose is usually normal, but it seems long as a result of the imbalance with the upper and lower skeletal thirds of the face; Also, the tip often droops and lacks the preferred projection. Most patients benefit from a rhinoplasty that includes osteotomies with in-fracture; the conservative reduction of the skeletal and cartilaginous dorsal hump; the removal of the cephalic portions of the lower lateral cartilages; and septal cartilage grafting (i.e., a caudal strut) sutured to the anterior septum to improve tip projection and definition. To achieve the most favorable aesthetic results, it is best to postpone the rhinoplasty until after effective orthognathic procedures have been performed. Exposure is provided through an open (i.e., columella-splitting incision) technique (see Chapter 38 and Fig. 27-9).

Facial Soft-Tissue Reconstruction

Despite several decades of well-intentioned surgical attempts to improve the soft-tissue deficiencies of the eyelid–adnexal regions, few aesthetically pleasing soft-tissue eyelid reconstructive results in patients with TCS have been reported.[64,82,83,129,135,143,148,156] The transposition of pedicled upper-eyelid-skin–muscle flaps to deficient regions of the lower eyelid is not technically difficult; unfortunately, the adnexal scarring that inevitably occurs often results in an "operated" look that generally detracts from any positive advantages of the procedure. The placement of full-thickness skin grafts to the lower eyelids is another frequently mentioned option. It predictably leaves a "patchy" look, and it should be reserved only for patients with recalcitrant corneal exposure problems. The lateral canthi are inferiorly displaced as a result of both orbital dystopia and hypoplasia of the lateral canthi and other components of the eyelid structures. Although the correction of the orbital dystopia and direct lateral canthopexies are helpful and should be carried out, they rarely normalize the multilevel soft-tissue hypoplasia of the specialized adnexal structures (i.e., skin, cartilage, eyelashes, ligament, fascia, and tendon). For these reasons, it is best to consult with an experienced oculoplastic surgeon when considering even minor eyelid procedures for patients with TCS.

The observed temporal fossa hollowing that is frequently encountered with TCS is also a reflection of multilevel hypoplasia that includes the skin, the temporoparietal fascia, the temporalis muscle, and the decreased bitemporal width of the anterior cranial vault. For this reason, transposing pericranial or temporoparietal congenital hypoplastic flaps will have limited utility for the management of either temporal or adnexal region subcutaneous deficiency.

When the procedure is meticulously designed and expertly executed, the transfer of soft-tissue flaps from other body regions, with microvascular reanastomosis, should be considered for reconstruction of TCS.[64,82,83,129,135,143,148,156] When this level of facial soft tissue replacement is required, parascapular free flaps have become the workhorse since they were first described by Dos Santos. Siebert and colleagues found that the parascapular flap allows for the reasonable correction of contour defects in the lateral aspects of the face; this yields improved aesthetic results in selected patients with TCS by providing vascularized soft tissue in the subcutaneous plane while minimizing scarring.[135] Fortunately, hypoplasia of the centrally located soft tissues of the face (i.e., forehead, nose, upper and lower lips, chin, and submental region) is not seen in patients with TCS. Dermal fat grafts, autogenous fat injections, and other forms of soft-tissue augmentation have gained popularity. The results of autogenous fat injection are variable and considered technique sensitive; they are generally not harmful, and they are clearly promising. Tanna and colleagues investigated the use of serial autologous fat grafting to restore soft-tissue contour in patients with hemifacial microsomia.[144] Patients with moderate to severe hemifacial microsomia were divided into two groups: Group I included those undergoing microvascular free-flap reconstruction (i.e., inframammary extended circumflex scapular flaps; n = 10); Group II included those undergoing multiple staged autogenous fat grafting (n = 21). The two patient groups had similar OMENS scores (2.4 and 2.3, respectively) and similar pre-reconstruction facial symmetry scores (74% and 75%, respectively). At the final evaluation, facial symmetry scores were 121% for the microvascular free-flap group and 99% for the fat-grafting group. Furthermore, no statistically significant difference between the microvascular and fat-graft groups in either patient or physician rating of overall satisfaction was noted. The extrapolation of these study results to the individual with TCS is appropriate.[52,73,144]

External Ear Reconstruction

The surgical reconstruction of the auricle can be satisfactorily achieved through a staged approach in the hands of a few experts.[12-15,19,40,74,75,86,111,130,140,145,146,155,162] The methods described by Brent represent the reference standard for external ear reconstruction.[12-15] The successful grafting of a well-sculpted cartilage framework is the foundation for sound auricular repair. According to Brent, most children have adequate rib cartilage for the repair by 6 years of age. At that time, the synchondrotic region of ribs 6 and 7 will provide an ample cartilage block to form the framework of the ear; this is taken from the side contralateral to the ear being constructed. With the use of the preoperatively

determined measurements and a prefabricated template, the position of the ear is determined, and a small preauricular incision is made. Unusable vestigial cartilage is excised. A thin-skinned pocket is developed, with the dissection carried beyond the marked auricular outline to recruit sufficient tension-free skin coverage. For patients with bilateral microtia, Brent prefers that the harvesting of cartilage grafts for each ear be separated by several months. Simultaneous bilateral auricular reconstruction would necessitate bilateral chest wounds with severe splinting and the potential for respiratory distress. Other stages of the auricular construction include lobule transposition; the detachment of the auricle with a skin graft; the management of the hairline; and tragus construction. Brent suggests that bilateral microtia repair be completed with five procedures that are carried out at 3-month intervals.

When completing microtia reconstruction in the patient with TCS, eventual external auditory canal and middle-ear surgery must be considered. Auricular construction should precede any middle-ear surgery because, after an attempt is made to open the canal, the chances of obtaining a satisfactory auricular repair are severely compromised as a result of the scarring of the skin envelope. When middle-ear surgery is an option, Brent suggests that the cartilaginous framework be sculpted with a wider concha to accommodate a future surgically created canal.

Other options for external ear reconstruction include the use of alloplastic and homologous frameworks. Alloplastic materials that are currently in use include silicone and Medpor (Porex Surgical, Inc., College Park, Ga). These foreign substances are more susceptible to infection, soft-tissue wound dehiscence, and susceptibility to minor trauma, even decades after reconstruction. Innovative techniques of tissue engineering involving bovine cartilage cells that are grown in the laboratory and seeded on a synthetic biodegradable ear template that is then implanted beneath the skin of an immunocompetent mouse have shown promise for the future. Unfortunately, until tissue engineering evolves beyond the currently encountered immunogenic problems, sculpted autogenous rib cartilage will remain the material of choice for the surgical repair of the ear.

At the same time, unless the option of sculpted autogenous rib cartilage is carried out by an experienced auricular reconstructive surgeon, the chance of achieving an aesthetically acceptable result is slim. For this reason, the use of a prosthetic external ear or no reconstruction at all in most individuals with TCS should not be discounted automatically.

External Auditory Canal and Middle-Ear Reconstruction

Although some of the hearing loss in the patient with TCS is attributable to external auditory canal stenosis or atresia, most of the loss (i.e., an average of 44 dB) is attributable to hypoplastic middle-ear cavities and ankylotic or missing ossicles.[18,58,66] Ankylosed or non-functioning ossicles appear to limit hearing conduction to the same extent as if they were absent.[55] Attempting reconstruction of the middle ear in patients with TCS can be expected to result in gains in hearing. However, even if the ossicles are mobilized, middle-ear dysmorphology remains; this results in residual hearing loss and leaves the patient dependent on some form of amplification. Jahrsdoerfer reported on a group of patients with TCS who underwent surgery for hearing rehabilitation.[66] He confirmed the generally unsuccessful attempts to satisfactorily improve "non-aided" long-term hearing. A form of bone-conduction hearing aid is required for proper amplification in most patients, including those who have undergone reconstruction as well as those who have not. The bone-conduction hearing aid may be a traditional unit, a modified amplification system, or a bone-anchored conduction unit.

According to Brent, for the gains from any middle-ear surgery to outweigh the risks and complications of the procedure, it should be reserved for selected patients with bilateral and unilateral microtia in whom personal motivation is high, in whom the favorable radiologic evidence of middle-ear development is present, and in whom a favorable outcome is expected according to an experienced otologist.[12-15] Furthermore, it must be planned through a team approach with an otologist and an auricular/reconstructive surgeon who are competent and experienced with ear-canal atresia, middle-ear malformations, and microtia repair. At the time of middle-ear surgery, the auricular/reconstructive surgeon initiates the procedure by lifting the reconstructed ear from its bed while carefully preserving both the connective tissue on the framework's undersurface and the overall circulation of the flap. The otologist proceeds by drilling a bony external auditory canal, completing ossiculoplasty, and then repairing the tympanum with a temporal fascia graft. The auricular/reconstructive surgeon then excises the soft tissues to exteriorize the meatus through the chondral region and harvests a skin graft that the otologist uses to line the new external auditory canal.

The Bone-Anchored Hearing Aid Option

A bone-anchored hearing aid (BAHA) consists of a permanent titanium fixture that is surgically implanted into the skull bone behind the ear and a small detachable sound processor that clips onto the fixture. BAHAs are suitable for people with conductive or mixed hearing loss who cannot adequately benefit from or prefer not to use conventional hearing aids.

Colquitt and colleagues completed a systematic review and an economic evaluation of BAHAs for people who are bilaterally deaf.[23] Previous prospective studies of adults or children with bilateral hearing loss were eligible for review. Twelve studies were included; there were seven cohort pre-post studies and five cross-sectional audiologic comparison studies. Comparisons were made between BAHAs and the

following: 1) conventional hearing aids, which are also known as air-conduction hearing aids (ACHAs); 2) bone-conduction hearing aids (BCHAs); and 3) unaided hearing and ear surgery. The study also looked at 4) unilateral versus bilateral BAHAs. Outcomes reviewed included hearing measures, validated measures of quality of life, adverse events, and measures of cost-effectiveness.

There appeared to be some audiologic benefits of BAHAs for this group of patients, including 1) improvements in speech as compared with BCHAs; and 2) understanding and noise as compared with ACHAs (however, ACHAs may produce better audiologic results for other outcomes). In addition, 3) hearing was found to be improved with the use of BAHAs as compared with unaided hearing; and 4) studies that compared unilateral with bilateral BAHAs suggested the benefits of bilateral BAHAs in many situations. However, prospective case series of BAHAs reported rates of 6.1% to 19.4% for the loss of the implants over time. In addition, the financial analysis suggests that BAHAs are unlikely to be a cost-effective option in terms of hearing gain and probability of needing alternative aids. Interestingly, the greater the benefit from aided hearing and the greater the difference in the proportion of people using the hearing aid for more than 8 hours per day, the more likely the BAHAs were a cost-effective option.

Janssen and colleagues completed a systematic review of bilateral BAHAs for bilateral permanent conductive hearing loss.[68] This was a review of the literature from between 1977 and 2011, and it included studies in which subjects of any age had permanent conductive hearing loss and bilateral implanted BAHAs. Eleven studies met the criteria for data analysis. Bilateral BAHAs were found to provide audiologic benefit as compared with unilateral BAHAs (i.e., improved thresholds for tones, speech in quiet and in noise, improved localization/lateralization, and patient's perceived subjective benefit). Disadvantages of bilateral BAHAs included 1) listening in noise in some condition; 2) presumed additional cost; and 3) presumed increasing adverse event risk. The authors concluded that bilateral BAHAs provided additional objective and subjective benefit as compared with unilateral BAHAs.

Conclusions

The current approach to the correction of malformations associated with TCS is to stage the reconstruction to coincide with facial growth patterns, visceral function (i.e., vision, breathing, chewing, swallowing, speech, hearing), and psychosocial needs. Precise morphologic analysis of each patient and the recognition of the need for a staged reconstructive approach serve to clarify the objectives at each interval for both the clinicians and the family. By continuing to define a rationale for the timing, methods, and extent of surgical, medical, and dental interventions and then objectively evaluating head and neck function, facial aesthetics, and psychosocial outcomes, the outlook for individuals affected by TCS will be greatly improved.

- Facial Soft-Tissue Reconstruction
- External Ear Reconstruction
- External Auditory Canal and Middle-Ear Reconstruction
- Conclusions

Hemifacial microsomia (HFM) is a craniofacial malformation that results in varying degrees of hypoplasia of the structures within the first and second branchial archs.[34,35,38,53,62,65,66,81,84,174,227] Congenital hypoplasia is generally unilateral, although bilateral (asymmetric) involvement occurs in 5% to 15% of patients. Most cases of this condition are sporadic, but there are rare familial causes that exhibit autosomal dominant inheritance. The term *hemifacial microsomia* was first used by Gorlin and Pindborg during the early 1960s, although the first recorded cases may have been those of Canton in 1861 and Von Arlt in 1881.[62] Many terms have been used for this malformation, thus indicating the wide spectrum of anomalies observed and emphasized by authors from various disciplines. In addition to HFM, the malformation has been called *craniofacial microsomia, oculo–auriculo–vertebral dysplasia, first and second branchial arch syndrome, lateral facial dysplasia, unilateral oto–mandibular dysostosis, facio–auriculo–vertebral sequence,* and *oculo–auriculo–vertebral spectrum.*

Although there are no agreed-upon minimal diagnostic criteria, the facial phenotype is characteristic when enough manifestations are present. In most patients, microtia or other auricular or preauricular abnormalities (i.e., preauricular tags or sinus pits) may present the mildest manifestation. Involvement is not always limited to the facial structures. Cardiac, renal, additional skeletal (vertebral), central nervous system, and other more unusual anomalies may also occur. Goldenhar syndrome is considered a variant of HFM, and it is present in about 10% of HFM patients. In addition to maxillofacial malformation, it presents with epibulbar dermoid cysts and cervical spine involvement.

Inheritance Pattern

The occurrence of HFM has been estimated to range from 1 in 3500 to 1 in 26,550 live births. Cohen suggests that the birth prevalence is likely to be around 1 in 5600 live births.[62,26] Morrison and colleagues stated a prevalence rate of conditions on the oculo–auriculo–vertebral spectrum of 1 in 45,000 in Northern Ireland.[26]

Kelberman and colleagues performed a genome-wide search for linkage in two families with features of hemifacial microsomia.[105] In one of these families, the data were highly suggestive of linkage to a region of approximately 10.7 cM on chromosome 14q32, with a maximum multipoint LOD score of 3.00 between microsatellite markers D14S987 and D14S65. Linkage to this region was excluded in the second family, thereby suggesting genetic heterogeneity. With the use of an animal model.

Poswillo demonstrated that early vascular disruption with expanding hematoma formation in utero resulted in the destruction of differentiating tissues in the region of the ear and the jaw.[214-218] The degree of local destruction

appeared to be related to the severity of tissue damage caused by the hematoma. The constellation of anomalies seen in patients with HFM suggests an origin that occurs at about 30 to 45 days' gestation. Naora and colleagues described a transgenic mouse line that carried an autosomal dominant insertion mutation that resulted in facial anomalies that resemble HFM, including microtia and abnormal occlusion.[164]

First and second branchial arch malformations similar to HFM have been observed in infants who are born to women who have been exposed to thalidomide and primidone. The administration of isotretinoin (Accutane) may also injure neural crest cells and prevent their normal development, thereby resulting in hemifacial hypoplasia similar to that observed in patients with HFM. It has been documented that acute exposure to ethanol during gastrulation (i.e., the transformation of the blastula into the gastrula) may induce asymmetric facial development.

Discordance in monozygotic twins has been frequently reported. Concordance with variable expression has also been rarely documented in monozygotic twins. The rarity of the reports of the concordance of the malformation in twins supports the suggestion that the condition is sporadic in most families. Familial instances have been observed with variable expressivity. Overall, the empiric recurrence risk is on the order of 2% to 3%; however, 1% to 2% of cases suggest an autosomal dominant inheritance pattern.

Engiz and colleagues reviewed the clinical and laboratory findings of 31 individuals with Goldenhar syndrome (15 boys and 16 girls) between the ages of 1 day and 16 years.[47] The characteristic features were preauricular skin tags (90%), microtia (52%), hemifacial microsomia (77%), and epibulbar dermoids (39%). Vertebral anomalies were noted in 70%, cardiac malformations were found in 39%, genitourinary anomaly were noted in 23%, and various central nervous system malformations were found in 47%.

Several classification systems for HFM have focused on one or more fundamental anatomic features of this anomaly. In 1991, Vento and colleagues described the OMENS classification for HFM. This system substratifies each of five anatomic manifestations of HFM in accordance with their dysmorphic severity on a scale from 0 to 3. The five manifestations each constitute one letter of the *OMENS* acronym: *orbital asymmetry; mandibular hypoplasia; ear deformity; nerve dysfunction;* and *soft-tissue deficiency.* Scoring was done on the basis of conventional radiographs (e.g., posteroanterior, lateral, submental, panoramic), physical examinations, and photographs. Although the OMENS classification does allow for the objective cataloguing of a range of the abnormalities that constitute the spectrum of HFM, it falls short in terms of providing effective communication when determining the timing and technique that are best suited for the reconstruction of each component of the anomaly (i.e., maxillo-mandibular, orbito–zygomatic, soft tissues, external ear). It also is of limited value with regard to overall patient management.[276]

At the present time, HFM should be regarded as a nonspecific symptom complex that is etiologically and pathogenetically heterogeneous.* Extreme variability of expression is the characteristic finding.

Considerations during Infancy and into Early Childhood

At the time of birth, for a child with HFM, concerns will center on the adequacy of the airway; swallowing and feeding; hearing; vision; the presence of other associated malformations; and family unit psychosocial issues.[3,16,27,28,56,57,112,125,131,165,175,193,196,197,199,207,208]

The *airway* may be compromised as a result of 1) maxillary hypoplasia with choanal (nasal) obstruction 2) mandibular micrognathia with a retropositioned tongue obstructing the oropharyngeal/hypopharyngeal spaces 3) laryngomalacia/tracheomalacia or 4) neuromotor involvement.[3,16,27,28,57,195] Depending on the severity of these malformations, a spectrum of airway problems may be present and necessitate treatment that ranges from special infant positioning with an extended hospital stay to mandibular osteotomies with advancement; on rare occasions, immediate or delayed tracheostomy may be required.

When the airway is compromised, the newborn has difficulty *swallowing* enough fluids and taking in enough calories (i.e., maintaining hydration and positive nitrogen balance) while simultaneously breathing effectively (i.e., sufficient oxygenation). In this situation, gavage-assisted feedings or the placement of a gastrostomy tube may be necessary to ensure adequate nutrition without aspiration or respiratory distress.

When a *cleft* (of the lip, palate, or both) or *macrostomia* is present, the timing of correction of these anomalies is generally similar to that used for the patient with nonsyndromic cleft lip and palate (Fig. 28-1).

Soon after birth, examination by a *medical geneticist* and the procurement of a blood sample for chromosomal studies (i.e., genetic analysis) will help to discern the extent of birth defects and the risk of recurrence. Evaluation by the *pediatric otolaryngologist* in combination with the *speech and feeding specialist* will clarify the extent of breathing, swallowing, and feeding difficulties. Initial *audiologic testing* via auditory evoked brain responses is essential to clarify neurosensory hearing function. A *pediatric ophthalmologic* assessment is useful to assess extraocular muscle function, corneal exposure difficulties, visual potential, and adnexal region malformations.

When moderate to severe skeletal malformations are present, a *craniofacial computed tomography (CT) scan* from the top of the skull through the cervical spine with three-dimensional reformation will be useful to document the extent of craniofacial skeletal dysmorphology. A focused *petrous temporal bone CT scan* is also required to document external auditory canal anatomy as well as middle and inner

ear anatomy. Because of the potential increased risk of radiation exposure to infants, these imaging studies may be delayed until they are necessary for surgical treatment planning. Appropriate *craniofacial, maxillofacial, cleft lip and palate, and auricular reconstructive surgeons* should also be consulted as indicated.

Dysmorphology Associated with Hemifacial Microsomia

Facial Soft Tissues

From a clinical perspective, the soft-tissue deficiencies associated with HFM can be considered to affect four anatomic regions of the head and neck: 1) the external ear; 2) the eyelid–adnexal structures; 3) the preauricular–cheek–lip soft tissues; and 4) the temporal fossa (Figs. 28-2 and 28-3).[19,51,85,98,101,106,130,133,129,228,251] The soft tissues within each region that may be deficient and dysmorphic include the bulk of the cutaneous and subcutaneous tissue, the volume of fat, the muscles of mastication and facial expression, the cranial nerves, and the parotid and submandibular glands.

According to the research of Kane and colleagues, in patients with HFM, the extent of hypoplasia of specific muscles of mastication frequently predicts the extent of dysplasia of the osseous origin and insertion of those muscles.[98] If the temporalis muscle is hypoplastic, a deficiency of the coronoid process will be present. When the masseter muscle is hypoplastic, the gonial region of the mandible will also be deficient. When the lateral pterygoid muscle is deficient, the condylar head is deficient or absent.

Preauricular–cheek region soft-tissue thickness and skin surface area are generally related to the skeletal deficiencies. *Skin tags* are small vestigial rests of epithelial tissue that are generally found at the cleft between the first and second arches. Skin tags are frequently associated with small cartilaginous remnants that are found within the subcutaneous tissue. *Sinus tracts* may form inclusion cysts or result in

• **Figure 28-2** A 9-year-old boy who was born with left-sided hemifacial microsomia and a unilateral cleft lip and palate. He underwent lip and palate repair during early childhood at another institution. He is congenitally missing the left external ear and external auditory canal. The soft tissues of the eyelids and the cheek region are also deficient. The skeletal malformation involves the upper facial skeleton (i.e., the left zygomatic complex, the left orbit, and the left squamous temporal bone) and the lower facial skeleton (i.e., the maxilla and the mandible). He has a type III glenoid fossa mandibular malformation. **A,** Frontal facial and computed tomography scan views. **B,** Oblique facial and computed tomography scan views.

infection if they are obstructed. *Macrostomia* is a clefting or failure of fusion of the maxillary and mandibular processes and of the first branchial arch, respectively. This results in a cleft of the orbicularis oris muscle, the overlying skin, and the underlying mucosa directly through the oral commissure. *Anophthalmia* or *microphthalmia* may also occur. *Colobomata* of the iris or eyelids with the absence of the eyelashes is a frequent finding. *Ptosis of the upper eyelid* (i.e., as a result of levator palpebral muscle function) with narrowing of the vertical palpebral fissure is often seen. *Deficiencies of the lateral canthi* with a decreased horizontal fissure are common.

Epibulbar dermoid cysts are found in a significant percentage of patients; they appear as solid yellowish or pinkish-white ovoid masses that vary in size from that of a pinhead to 8 to 10 mm in diameter. The cysts occur most often at the inferotemporal quadrant of the limbus. The surface is usually smooth, and it frequently has fine hairs. These cysts can occur at any location on the globe or in the orbit, and they may be movable or fixed to the dermis. Unilateral epibulbar dermoid cysts are seen in a high percentage of patients, and multiple lesions may occur in each eye. Occasionally, vision is impaired by encroachment on the pupillary axis or by lipid infiltration of the cornea.

Abnormalities of the external ear are a consistent finding and range from *anotia* to a *mildly dysmorphic ear*. Farkas and James were unable to demonstrate a direct relationship between the degree of microtia and the extent of skeletal deformity.[51]

The External Auditory Canal, the Middle- and Inner-Ear Structures, and Audiologic Findings

A narrow external auditory canal is frequently found in patients with mild external ear deformity, whereas atretic canals are expected in more severe cases.[17,18,223,280] At times, a small external ear with normal middle-ear architecture is seen. Audiometry will delineate the nature of the hearing loss, which likely includes conductive and, less frequently,

• **Figure 28-3** A 14-year-old girl who was born with right-sided hemifacial microsomia, including microtia and an absent external auditory canal. There is soft-tissue deficiency on the right side of the face. The skeletal malformations involve the right zygomatic complex as well as the mandible and the maxilla. There is a Type IIB mandibular malformation. The patient had previously undergone right ear reconstruction and the placement of a bone-anchored hearing aid (BAHA) at another institution. **A,** Frontal facial and computed tomography scan views. **B,** Oblique facial and computed tomography scan views.

sensorineural loss in 15% of patients. Hypoplasia or agenesis of the ossicles may occur. In a comprehensive study, Caldarelli and colleagues used air and bone conduction audiometry and temporal bone tomography to evaluate 57 patients with hemifacial microsomia.[17,18] The authors were unable to correlate the degree of auricular (i.e., external ear) deformity with hearing function. Focused temporal bone CT scans offer the best documentation of the middle-ear structures. Assessment of the unaffected and presumed normal ear is an essential part of the evaluation.

Maxillomandibular Region

A variable degree of hypoplasia of the skeletal structures within the first and second branchial arches will occur. As a result, the anteroposterior, transverse, and vertical dimensions of the face are diminished on the affected side, with secondary deformities on the contralateral side. This is especially true in the maxillomandibular region (see Figs. 28-2 and 28-3).[134]

Cranio–Orbito–Zygomatic Region

A variable degree of hypoplasia of the zygomatic complex is a frequent finding. The consequences of zygomatic hypoplasia may be seen clinically as orbital dystopia; maxillary hypoplasia; deficiency of the glenoid fossa; and deficiency of the squamous aspect of the temporal bone. This is best visualized with a three-dimensional reconstruction of a craniofacial CT scan. As a result of the asymmetric nature of the deformity, identifying consistent reproducible landmarks is difficult in the upper face. This makes a quantitative assessment of the skeletal malformation difficult and imprecise.

Facial Growth Potential with Hemifacial Microsomia

The potential for longitudinal facial growth in a child who is born with HFM is an important factor when

considering the timing and techniques of reconstruction.[96,97,114,115,133,144-147,152-154,168,194,202-204,225,226,230-232] An additional pivotal consideration for the maxillofacial reconstruction of the individual with HFM is the integrity of the glenoid fossa–condyle–ascending ramus of the mandible (Fig. 28-4). Some authors speculate that a reduced mandibular growth potential secondarily leads to the observed maxillary deficiency on the ipsilateral side with progressive canting of the occlusal plane. Those who advocate mandibular surgery during the mixed dentition often do so with the belief that it will effectively correct the lower jaw malformation and that normal ongoing mandibular growth will continue with the prevention of secondary maxillary growth deformities in an otherwise normal upper jaw. There are objective clinical and radiographic studies in the literature that review the issue of the progression of deformity with HFM during growth.[87-89,194,225,226]

Rune and associates placed metallic implants in the jaws to study the facial growth of 11 patients with HFM.[225,226] They collected and studied serial roentgen stereophotogrammetry images from each patient. They found that, in five patients, the cant of the occlusal plane seemed to "slightly" increase; in the remaining six patients, the occlusal plane asymmetry either remained the same or improved with time. The authors also stated that the pattern of mandibular displacement showed no correlation with the severity of the presenting deformity. They concluded that the data "do not support the claim that the asymmetry of the jaws is invariably increased in time because of growth disparity between the affected and the unaffected sides."[225,226]

Polley and associates completed a longitudinal radiographic cephalometric study of the maxillofacial region in patients with HFM.[194] Twenty-six patients were included in the study and were followed longitudinally. Five patients (19%) had a Pruzansky grade I mandibular deformity, 14 patients (54%) had a Pruzansky grade II deformity, and 7 patient (27%) had a Pruzansky grade III deformity. The average age at the time that the initial cephalometric records for all patients were obtained was 3.5 years (range, 0.7 to 9.2 years), and the average age at the time that the final cephalometric records were obtained was 16.7 years (range, 10.1 to 22.5 years). None of the study patients had undergone surgical or orthopedic jaw manipulation during the time of the study, although nine patients underwent fixed appliance orthodontic treatment. Vertical and horizontal skeletal mandibular asymmetry was evaluated with posteroanterior cephalometry. The authors found that the growth of the affected side in patients with HFM parallels that of the contralateral side. The degree of mandibular asymmetry in the study patients remained relatively constant throughout craniofacial development. The mandibular skeletal deformity as measured in the study subjects did not progress with time. The growth rate of the affected side was similar to that of the contralateral side in each subject, irrespective of the degree of presenting mandibular deformity on the involved side. In the study group, subsequent growth occurred in both mandibular rami in each patient. This was true for all patients, irrespective of the Pruzansky grade and the side of the mandible that was affected.

Meazzini and colleagues conducted a long-term facial growth study of children affected by HFM with Type I or Type II mandibular malformations.[136A] The study group (N = 8) was not subjected to any treatment until adulthood. With the use of the panoramic radiograph analysis of ramus vertical heights, data confirmed that facial proportions in patients with HFM were maintained throughout growth when no treatment was undertaken. The authors concluded that HFM does not progress in the degree of facial asymmetry or deformity when left to mature naturally.

Ongkosuwito and colleagues studied mandibular growth in 84 consecutive patients with a confirmed diagnosis of unilateral HFM. The mandibular malformation for each subject was categorized into one of four grades on the basis of the Pruzansky/Kaban classification. The malformations were then regrouped to reflect those with a functional glenoid fossa and condyle (Type I and Type IIA) and those without (Type IIB and Type III). The study groups were compared with a normal age-matched Danish control group. For each subject, an orthopantomogram was obtained and used to perform measurements of ramal height (i.e., the distance measured in millimeters between the condylion and the gonion) on each side. The data confirmed that patients with HFM start with a shorter ramal height and end up with a shorter ramal height, although growth is the same in both patients with HFM (regardless of the extent of malformation) and controls. In patients with HFM, the ramal height is smaller on both sides, which means that growth is characterized not simply by unilateral underdevelopment but by a complex three-dimensional phenomenon.[161A]

According to the independent findings of Polley and colleagues, Rune and colleagues, Meazzini and colleagues, Ongkosuwito and colleagues, *the mandibular asymmetry associated with HFM is not progressive.* In these studies, progressive canting of the maxillary plane was not routinely observed (Figs. 28-5 through 28-7).

An alternative perspective is presented by **Kaban and colleagues.**[92,93,95] Their research suggests to them that, as a result of ongoing growth after birth in patients with HFM, there is progressive canting measured at the pyriform rims, the occlusal plane, and the intergonial angles, especially with the Type IIB and III mandibular malformations. The authors recommend that mandibular reconstruction during the mixed dentition be considered to correct the lower jaw deformity in anticipation of normal ongoing longitudinal growth; to prevent secondary maxillary deformities (in an otherwise normal maxilla); and to alleviate psychosocial issues that would otherwise occur during childhood. I believe that Kaban and colleagues' rationale for first-stage mandibular reconstruction during the mixed dentition in children with HFM are overly optimistic.

1. In perspective, even if a small degree of asymmetric jaw growth occurs during childhood in the patient with HFM, significant progressive dysfunction (i.e., in the areas of chewing, breathing, speech, lip control, or swallowing) that would justify a first-stage mandibular procedure is not generally seen.
2. The effectiveness of a first-stage mandibular procedure during the mixed dentition as a definitive long-term maxillofacial reconstruction has not been documented. Not only would a successful initial lengthening and derotation of the mandible be required, but the fabrication and then the periodic modification of an effective removable acrylic splint to create and maintain an ipsilateral posterior open bite (to allow for the supra-eruption of the maxillary posterior teeth) would be needed. The necessity of constant clinician monitoring and splint modification in conjunction with ongoing orthodontic treatment and rigorous patient compliance would be essential. This requires an experienced and dedicated orthodontist, a persistent surgical coordinator, and a zealous patient and family. All of the treating clinicians and the family must be in close geographic proximity and without socioeconomic barriers to treatment. Unfortunately, this is not a combination of events that is readily achievable.
3. Unfortunately, the costochondral graft construction of the neocondyle–ascending ramus required for the treatment of HFM Type IIB and III mandibular deformities carried out during the mixed dentition will result in a significant percentage of poorly growing mandibles (i.e., overgrowth or undergrowth). At minimum, a second definitive orthognathic reconstruction will be required (see the section to follow in this chapter about costochondral grafting).
4. Researchers have documented that, when a distraction osteogenesis (DO) approach is used as a first-stage mandibular procedure for HFM during the mixed dentition, symmetric lower jaw growth does not occur. The resulting residual mandibular asymmetry and deformity will, at minimum, require later

NOTE: In this author's view, the benefits of mixed-dentition first-stage mandibular procedures rarely outweigh the downsides. The argument that first-stage mandibular surgery during the mixed dentition is necessary to allow the child to develop normal self-esteem is well intended but not realistic. Multiple doctor visits and procedures give a child a "sick kid" mentality and draw more attention to his or her differences.[199] The unfortunate reality is that, for a majority of HFM patients even with well-done mixed dentition first stage mandibular reconstruction, the residual external ear, soft tissue, and other skeletal malformations will continue to draw attention to the child's facial disproportion. The overall burden of care for the patient, the family, and the health care system is minimized when definitive single-stage maxillomandibular reconstruction is carried out at the time of early skeletal maturity (i.e., between the ages of 13 and 15) in conjunction with orthodontic treatment.

definitive orthognathic reconstruction. In addition, the completion of a mandibular ramus–body osteotomy and DO during the mixed dentition is documented to result in the destruction of ipsilateral developing permanent molars in a significant percentage of children who have undergone such an operation.

Classification of Temporomandibular Joint–Mandibular Malformation

The extent of temporomandibular joint (TMJ)–mandibular deficiency is an important factor when considering the timing of and techniques for reconstruction.[108,118,119,249] Imprecise definitions of the degrees of TMJ–mandibular anomalies have resulted in miscommunication among clinicians and in the literature. In an article published during the late 1960s, Pruzansky classified the presenting

mandibular anomalies of HFM into three grades (Type I through Type III) in accordance with the extent of hypoplasia of the mandibular condyle and ramus.[220] Kaban and colleagues refined the Pruzansky classification to further clarify the degree of glenoid fossa–condyle–ascending ramus malformation observed in patients with HFM.[94,157] The Kaban classification provides an excellent starting point for defining the reconstruction required in each individual patient (see Fig. 28-4).

A **Type I** mandible has only a minimal degree of hypoplasia of the glenoid fossa, the condyle, and the ascending ramus (see Fig. 28-4, *A*). All of the skeletal components are present, all of the masticatory muscles are present, and function is within normal limits. There is a degree of asymmetric mandibular retrognathia, with a shift of the chin off of the facial midline. A limited degree of maxillary cant can usually be documented. Note: With Type I malformations, the condyle and the glenoid fossa are fully intact. There is no need to construct a new condyle or a new glenoid fossa.

A **Type IIA** mandible has a moderate degree of glenoid fossa and condyle–ascending ramus hypoplasia (see Fig. 28-4, *B* and *C*). By definition, the extent of hypoplasia results in the TMJ complex being located anteriorly and medially as compared with the normal side; however, joint function remains satisfactory. The masticatory muscles have a variable degree of hypoplasia. The mandible is retrognathic, the chin is shifted to the ipsilateral side, and an anterior open bite is frequently seen. A moderate maxillary cant is usually present. With a Type IIA malformation, despite significant hypoplasia, a decision to retain the TMJ complex (i.e., the condyle and the glenoid fossa) as part of the maxillomandibular reconstruction has been made.

The **Type IIB** mandible involves severe hypoplasia of the condyle–ascending ramus (see Fig. 28-4, *D*). The glenoid fossa has an anterior and medial location, but its placement is adequate for the construction of a neocondyle. The hypoplastic condyle, if it is present at all, is rudimentary and not substantial enough to seat into the glenoid fossa. There is not a consistent "posterior stop" to the mandible against the glenoid fossa. The mandible functions with rotation but not with a condylar component in the glenoid fossa, and there is little or no translational jaw movement. Vertical mouth opening is present (albeit reduced), with a shift of the chin to the ipsilateral side. The extent of mandibular dysmorphology, asymmetric retrognathia, and anterior open bite is marked. Variable but definite deficiencies of the masticatory muscles are present. There is usually significant hypoplasia of the ipsilateral maxilla, with obvious canting. By definition, with a Type IIB mandibular deficiency and deformity, the condylar remnant is too far displaced and rudimentary to be useful. Construction of a *neocondyle–ascending ramus* into the current acceptable glenoid fossa is required.

The **Type III** mandible is free-floating on the ipsilateral side, with no "posterior stop" of the lower jaw against the skull base on the affected side (see Fig. 28-4, *E*). The condyle and all or part of the ramus on the ipsilateral side are absent. The disc, the TMJ capsule, and the glenoid fossa are also not developed. Mandibular dysmorphology is severe and includes ipsilateral retrognathia and decreased posterior (ramus) facial vertical height. The masticatory muscles are severely hypoplastic, and the lateral pterygoid remnant is not attached to the mandibular structures. There is significant hypoplasia of the maxilla, with obvious canting. Occasionally, a tracheostomy is required shortly after birth to manage the airway compromise that results from a combination of factors, including (but generally not limited to) the degree of mandibular hypoplasia. By definition, with a Type III glenoid fossa–mandibular malformation, the eventual construction of both a *neo–glenoid fossa* and a *neocondyle ascending ramus* will be required to achieve successful maxillofacial reconstruction.

Staging of Skeletal Reconstruction: Timing and Techniques

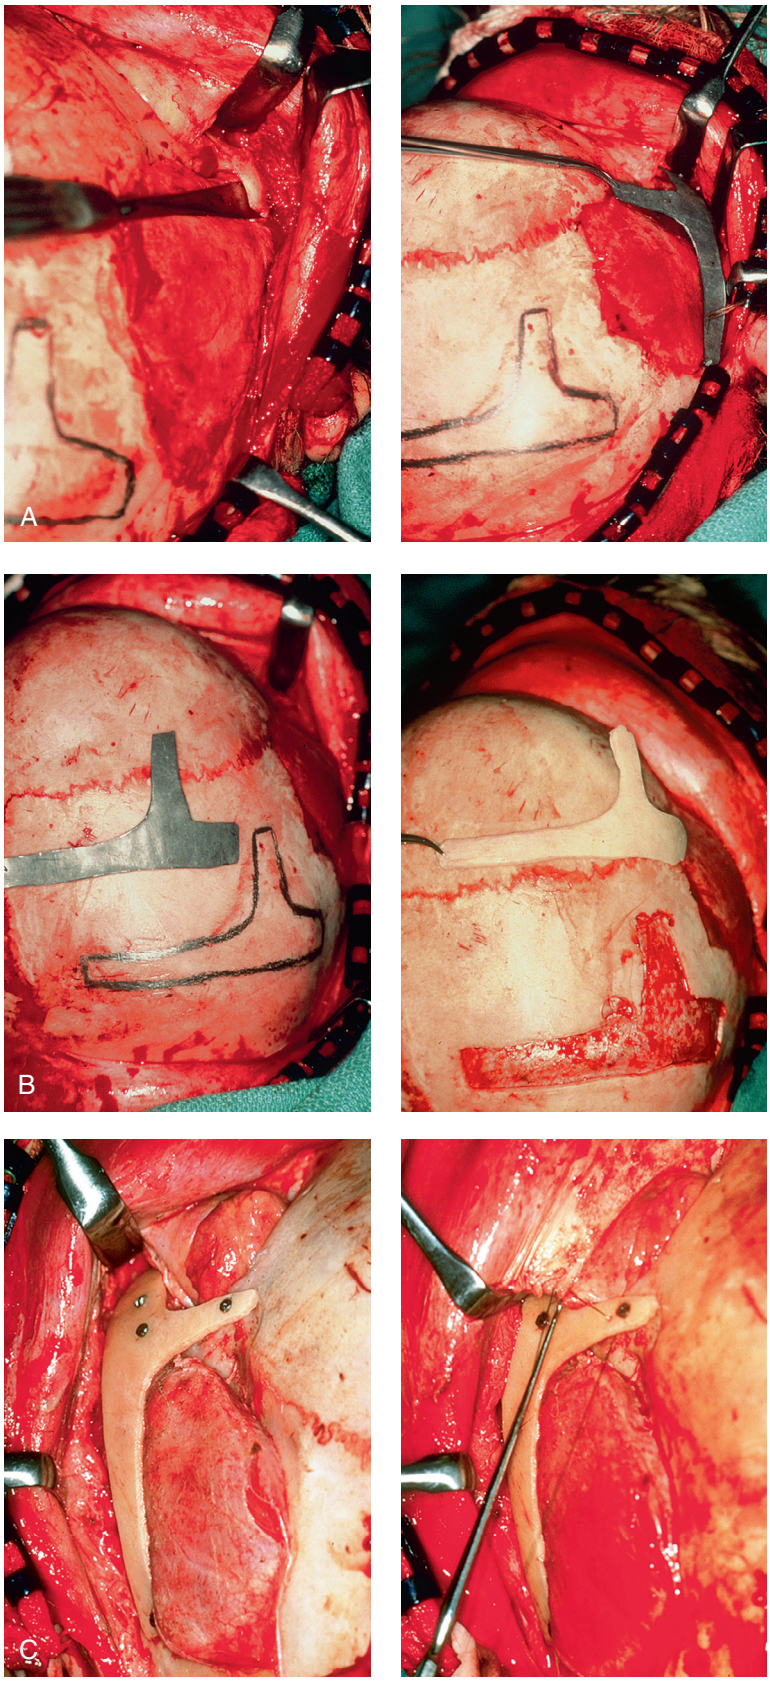
The facial rehabilitation of the patient with HFM must address unique and specific components of the malformation that may include the following: 1) the zygomatic and orbital region; 2) the maxillomandibular regions; 3) the facial soft tissues; 4) the external ear; 5) the auditory canal; and 6) the middle-ear structures.*

Some clinicians have speculated that there is a reduced facial growth potential in patients with HFM which then leads to a progression of the primary malformation and secondary deformities of the maxillofacial skeleton. This assumption has led some to advocate early mandibular reconstruction to prevent progression. This author agrees with Rune and colleagues,[225,226] Polley and colleagues,[194] Meazzini et al.[136A] and Ongkosuwito and colleagues[161A] that the observed facial asymmetry in patients with HFM is not progressive with ongoing growth (see the section earlier in this chapter about facial growth potential with HFM) (Figs. 28-5 through 28-7).[203,209-212,233,234]

Zygomatic and Orbital Reconstruction

The benefits of thoughtfully timed and meticulously executed orbito–zygomatic reconstruction for the patient with HFM are often underappreciated.[209-213] When upper face (i.e., orbito–zygomatic) reconstruction is needed, it is carried out through a coronal scalp incision. Correction of the upper face skeletal deformity may require the intracranial disassembly and reconstruction of the dysmorphic ipsilateral anterior cranial vault; the squamous portion of the temporal bone; and the lateral orbit regions with complete construction of the zygomatic complex, including the glenoid fossa. The use of full- and split-thickness cranial bone grafts is required (Fig. 28-8).

*References 70, 76, 77, 92-95, 99, 109, 135, 137, 142, 145, 151, 157, 166-168, 170, 172, 236, 243, 253, 256, 266, 270-275, 277, 287



• **Figure 28-8** Intraoperative views of a 7-year-old child demonstrate the technique of zygomatic–orbital reconstruction as described in this chapter. When working through a coronal scalp incision, the zygomatic and orbital structures are exposed. A full-thickness cranial bone graft is harvested, and a zygomatic complex is crafted from this. The crafted zygoma is inset and stabilized with microplates and screws. The orbital defects are reconstructed as indicated with cranial bone graft, and the orbital rim is reshaped with a rotary drill. A lateral canthopexy is completed through the coronal incision and fixed to the new frontozygomatic suture region. **A,** View of the dissected rudimentary zygomatic remnant. A template of the proposed zygomatic complex had been made. **B,** The template is taken to the temporoparietal region of the skull, and its outline is marked out for craniotomy. Through a craniotomy, a full-thickness cranial bone graft is harvested for zygomatic complex reconstruction. **C,** The full-thickness cranial bone graft is fixed in place with microscrews. The lateral canthus is identified through the coronal incision, and a 28-gauge stainless steel wire is passed through it. The lateral canthus is pexied to the new frontozygomatic region. *From Posnick JC, Goldstein JA, Waitzman AA: Surgical correction of the Treacher-Collins malar deficiency: quantitative CT scan analysis of long-term results,* Plast Reconstr Surg *92:12-22, 1993.*

This author believes that the reconstruction of the cranial vault, malar, and orbital deficiencies before the age of 7 years is not indicated unless functional disability warrants it.[213] After the patient reaches this age, cranio–orbitozygomatic skeletal development is nearly mature. When indicated, an adult-sized anterior cranial vault, orbit, and zygomatic complex may be constructed and matched with the contralateral normal side with little concern about how future growth will alter the initial results achieved. Donor site skull reconstruction is also simpler after the age of 7 years than it is in younger children, because the presence of bicortical cranial bone will facilitate the splitting of the inner and outer tables for efficient reconstruction. Artificial bone material may also be used to reconstruct the graft donor site of the posterior skull (see Chapter 27).

Other surgeons have recommended variations in the methods and timing of the reconstruction of the upper face skeletal anomalies associated with HFM.[31] Posnick and colleagues confirmed that the construction of the complete zygomatic complex with full-thickness autogenous cranial bone maintains volume and shape better than onlay grafts, which have been universally disappointing. Over time, onlay autogenous bone grafts that have been placed in the craniofacial region (e.g., supraorbital ridge, zygoma, anterior maxilla, angle of mandible, chin) from all tried donor sites (e.g., skull, hip, rib) have demonstrated significant and unpredictable resorption. Furthermore, no commensurate growth (i.e., volume expansion) of the graft with the underlying bone (e.g., the zygoma) should be expected. Some feel that, even if the onlay graft partially resorbs, at least something has been gained; however, this philosophy should be abandoned, because surface irregularities result in secondary deformities that further detract from the baseline malformation.

Maxillomandibular Reconstruction

An essential consideration when choosing the timing and techniques for maxillomandibular reconstruction in a patient with HFM is an understanding of the presenting TMJ–mandibular anatomy.[2,6,7,20,25,30-32,43,46,59,96,97,180,209-212,226] The classification of the TMJ–mandibular malformation, which was described earlier in this chapter, is clinically relevant and facilitates communication.[94,157] In the patient with HFM with either a Type I or Type IIA malformation, the basic maxillomandibular skeletal asymmetry and dysmorphology that requires reconstruction include the following: 1) degrees of altered facial height (i.e., decreased posterior facial height on the ipsilateral side); 2) diminished horizontal projection (i.e., deficiency more prominent on the ipsilateral side); and 3) decreased facial width (i.e. deficiency on the ipsilateral side). These malformations frequently result in canting (i.e., roll orientation) of the pyriform apertures, the maxilla, and the gonial angles; the shifting of the maxillary, mandibular, and chin midlines off of the facial midline (i.e. yaw orientation); clockwise rotation of the occlusal plane (i.e., pitch orientation); and an asymmetric class II malocclusion often with anterior open-bite malocclusion. According to the classification described, a patient who presents with a Type IIB malformation requires the *construction of a neocondyle*. For the individual with a Type III malformation in addition to this, there is a need for the *construction of a neo–glenoid fossa*.

The most favorable long-term function (i.e., speech, swallowing, chewing, breathing) and enhanced facial aesthetics are generally achieved in patients who undergo definitive reconstructive surgery of the maxilla, mandible, and chin regions at any time after jaw maturity (i.e., at 13 to 15 years of age for the HFM patient); this should be carried out in combination with effective orthodontic treatment after the permanent teeth have erupted and before the patient graduates from high school. As with other dentofacial deformities, extractions may be required to orthodontically relieve dental root crowding and to normalize the inclination of the anterior teeth in preparation for the surgical repositioning of the jaws.

Type I and IIA mandibular malformations are best reconstructed after all of the permanent teeth have erupted and orthodontic goals have been reached (see Fig. 28-4, *A, B,* and *C*). Surgical objectives can be met by making use of sagittal split ramus osteotomies of the mandible in combination with Le Fort I osteotomy (often in segments) and osseous genioplasty. This combination represents standard techniques, and it does not require bone grafts. The success of reconstruction is dependent on approximating mirror-image symmetry and Euclidian proportions of the skeleton through orthognathic procedures.

For **Type IIB** mandibular malformations, costochondral graft reconstruction of the deficient condyle ascending ramus at the time of skeletal maturity remains this surgeon's preferred approach in most cases (see Fig. 28-4, *D*), despite its limitations (see the section to follow concerning condylar reconstruction with the use of costochondral graft). A sagittal split ramus osteotomy is completed on the contralateral side to derotate the distal mandible. This is combined with a Le Fort I osteotomy (often in segments) and an osseous genioplasty.

A ramus osteotomy of the contralateral side of the mandible is completed first to control repositioning of the distal mandible. The distal mandible is then secured to the maxilla via intermaxillary fixation through a custom designed acrylic splint to create the preferred reorientation of the lower jaw (see Chapter 14). It may be necessary to resect the ipsilateral coronoid process before repositioning the distal mandible. The contralateral ramus osteotomy is then rigidly fixed with bicortical screws. The ipsilateral proximal mandible is reconstructed with the autogenous costochondral graft. Harvesting the rib graft from the contralateral chest wall provides the best contour for mandibular reconstruction. The fixation of the rib graft to the native distal mandible is accomplished with a titanium miniplate and 2.0-mm or 2.3-mm screws. The fixation plate extends from the graft forward along the

inferior border of the body of the mandible (fig. 28-15). It is generally necessary to recontour (i.e., with a bur on a rotary drill) the outer cortex of the distal mandible before onlaying the graft. Graft placement and fixation is often carried out through an extraoral Risdon neck incision. The avoidance of intraoral incisions on the ipsilateral mandibular ramus region during this procedure may minimize the incidence of infection. The effective seating of the neocondyle in the glenoid fossa is a critical step for successful reconstruction. In some patients, the extent of associated soft-tissue and skeletal deficiency will favor use of a vascularized fibula composite flap over the use of a costochondral graft.

The **Type III** glenoid fossa–mandibular malformation requires the surgical construction of the congenitally missing parts (see Fig. 28-4, *E*). The mandibular reconstruction is generally carried out as previously described for the Type IIB deformity. When the glenoid fossa requires construction (i.e., with a Type III malformation), so will the zygomatic complex. The glenoid fossa–zygoma and orbital reconstruction are best carried out as a separate operation when the patient is at least 7 years old (see the previous section about orbito–zygomatic reconstruction) and before mandibular reconstruction. With regard to the mandibular reconstruction, the deficiency of both the condyle-ascending ramus and the associated soft tissues may benefit from a vascularized fibula composite flap rather than a costochondral graft.

Consideration of First-Stage Mandibular Reconstruction during the Mixed Dentition

Personal Perspective Concerning First-Stage Mandibular Reconstruction during Childhood

The maxillofacial malformations in patients with HFM may be severe enough that, for airway or psychosocial reasons, the clinician feels compelled to recommend first-stage mandibular reconstruction during the mixed detention (i.e., between the ages of 7 and 11 years). Reported options for first-stage mandibular reconstruction in patients with HFM generally include 1) a ramus/body osteotomy followed by DO carried out over time for Type I and Type IIA malformations or 2) costochondral grafting with the immediate construction of a neocondyle ascending ramus for Type IIB and Type III malformations. In either case, derotation of the mandible to position the chin in the facial midline with the creation of an ipsilateral posterior open bite is usually considered the objective. The reconstructive option selected (i.e., costochondral graft versus DO) should be based on the presenting malformation and then on the following: 1) the three-dimensional morphologic results believed to be achievable; 2) the anticipated ongoing growth potential after surgery; 3) the differences in perioperative morbidity among the techniques; and 4) the overall burden of treatment to the patient, the family, the clinicians, and the health care system.[209-212]

Interestingly, most published reports of first-stage mandibular reconstruction in patients with HFM do not fully clarify the details of the presenting dysmorphology of the native glenoid fossa and condylar components before surgery (Figure 28-9). As stated, for DO to be effective, a functional glenoid fossa and an adequate condyle must be present (i.e., in the presence of Type I or Type IIA malformation). Unfortunately, a high incidence of bony and fibrous ankylosis has been reported in conjunction with mandibular DO in HFM.[49] In addition, the consistent occurance of "undergrowth" after mandibular DO reconstruction carried out during the mixed dentition was confirmed by Meazzini and colleagues.[143] Those authors conducted a comparison study of long-term follow up until the completion of facial growth of two homogenous samples of children with HFM. The experimental group was treated with mandibular DO during the deciduous or early mixed dentition in an attempt to correct the mandibular deformity. The control group was not subjected to any treatment until adulthood. The experimental group included children (n = 14) who underwent mandibular ramus osteotomies with DO (mean age, 5.9 years) with a mean follow up of 11.2 years. With the use of quantitative measurements on serial panorex radiographs, the DO group was compared with the control group (n = 8). The study results document that facial proportions in patients with HFM are maintained throughout growth when no treatment is undertaken. Unfortunately, after ramus osteotomies with DO, the mandibular disproportions returned to their original level of asymmetry during growth. The authors concluded the following: 1) HFM does not progress with regard to the degree of facial asymmetry or deformity when the patient is left to mature naturally and 2) early intervention with mandibular ramus osteotomies and DO does not effectively reduce long-term facial asymmetry in the patient with HFM.

Ongoing problems when choosing the costochondral graft option to be carried out during the mixed dentition for the Type IIB or III malformation include overgrowth, undergrowth, ankylosis, and resorption of the mandible (Fig. 28-10). The overgrowth concerns are diminished but not eliminated when the costochondral graft procedure is carried out in a child who is in the late mixed dentition stage (i.e., 9 to 11 years old) and in whom only a minimum amount of cartilage (i.e., ≈2 mm) is left at the articulating surface of the graft (see section to follow concerning condylar reconstruction with costochondral graft).

If a first-stage mandibular procedure is carried out during the mixed dentition for the Type IIB or III malformation, then the need for definitive mandibular reconstruction in conjunction with a Le Fort I maxillary osteotomy and an osseous genioplasty at the time of skeletal maturity should be anticipated.[3,16,28,27] The idea of carrying out a mixed dentition mandibular reconstruction to avoid definitive

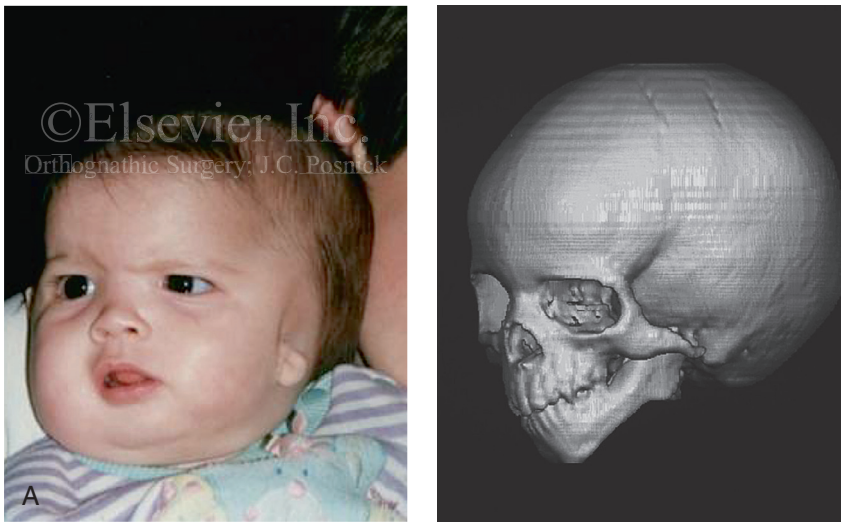
• **Figure 28-9** A Hispanic girl who was born with a mild form of left-sided hemifacial microsomia. The mandibular malformation was Type I. At another institution, she underwent a mandibular distraction procedure when she was 4 years old with an external device; the goals were to "derotate" the mandible, to shift the chin to the midline, and to create a posterior open bite. An acrylic splint was then used in an attempt to hypererupt the maxillary molars over time. The patient is shown at the time of procedure and then 7 years later after her referral to this surgeon. Unfortunately, the procedure carried out did not improve the occlusion or correct the facial asymmetry. During the process, the left mandibular permanent molars (i.e., the first, second, and third molars) were injured, and secondary deformities of the mandible also resulted. **A,** The child is shown when she was 4 years old, during the mandibular distraction. **B,** She is also shown at 7 years of age note the distortion and deformity of the mandible and the facial scarring. **C,** Residual malocclusion as a result of the external distraction. **D,** Panorex radiograph taken when the child was 11 years old (i.e., 7 years after the distraction) that illustrates the injuries to the first, second, and third permanent molars on the distracted side.



• **Figure 28-10** A newborn with left-sided hemifacial microsomia. She had a good airway as well as swallowing and chewing abilities. She was treated at another institution until she was referred to this surgeon when she was 15 years old. **A, B,** and **C,** Facial and computed tomography (CT) scan views taken during infancy that indicate microtia with an absent external auditory canal, hypoplasia and clefting through the zygomatic arch, and mandibular malformation (Type IIB) with a shortened posterior facial height and a rudimentary condyle.

3 years of age

5 years of age

• **Figure 28-10, cont'd D,** Frontal and CT scan views taken when the patient was 3 years old indicate no progression of the malformation. **E,** The same child when she was 5 years old just before undergoing a mandibular procedure at another institution. At surgery the mandible was derotated to shift the chin to the midline with the creation of a posterior open bite on the ipsilateral side. A costochondral graft was harvested and used to reconstruct the left condyle ascending ramus. An acrylic splint was then worn for several years in an attempt to "grow" the left maxilla and relieve the posterior open bite. The external ear was later reconstructed, but with suboptimal results.

15 years of age

15 years of age

• **Figure 28-10, cont'd F, G, H,** and **I,** Facial and CT scan views of the patient when she was 15 years old, at the time of referral to this surgeon (i.e., 10 years after costochondral grafting) and without other interventions. There has been extensive overgrowth of the costochondral graft previously placed on the left side of the mandible. This has negatively altered (distorted) the growth of the whole mandible and the maxilla, and it has also resulted in limited mandibular mobility. There is gross distortion of the entire face, with negative effects on the airway, speech articulation, chewing ability, lip closure/posture, and self-esteem.

• **Figure 28-10, cont'd J, K, L,** and **M,** Comparable CT scan views are shown when the patient was 3 years old (i.e., before rib grafting) and at the age of 15 years (i.e., 11 years after rib grafting).

maxillomandibular orthognathic reconstruction during adulthood is generally unrealistic.

The rationale for postponing the correction of the dentofacial deformity until the time of "early" skeletal maturity is the same as that for the correction of the jaw deformity associated with a repaired cleft palate and most other routine dentofacial deformities (e.g., long face growth pattern, primary mandibular deficiency, maxillary deficiency in combination with relative mandibular excess). This rationale includes the consideration of the following: 1) avoiding injury to the developing permanent dentition and the inferior alveolar nerves 2) avoiding soft-tissue scarring 3) avoiding the loss of ramus marrow space that will complicate the success of necessary redo ramus osteotomies 4) minimizing negative psychosocial memories of earlier jaw surgery that may prevent the patient and family from later pursuing definitive reconstruction and 5) avoiding the iatrogenic three-dimensional deformation of the mandible that limits long-term success. In addition, any orthodontics carried out during the mixed dentition will not be reflective of the permanent dentition; a final course of braces would also be required.

Patients with HFM who have a significant degree of vertical, horizontal, and transverse maxillary deformity will also require Le Fort I maxillary osteotomy in segments. No lesser approach will be sufficient. The surgical objectives of the upper jaw surgery may include the following:

1. *Cant correction of the maxilla* with the asymmetric intrusion of the anterior maxilla to establish a more normal upper lip–to–tooth relationship in repose and during smiling as well as to improve lip competence (i.e., roll orientation)
2. *Correction of the maxillary dental midline to the facial midline* with control of the yaw orientation to achieve an improved cheek region appearance and a better angle of mandibular symmetry
3. Either extrusion or intrusion of the posterior maxilla on each side, depending on the extent of *counterclockwise rotation* required to achieve adequate horizontal projection of the mandible and chin (i.e., pitch orientation)
4. *Widening of the maxilla* (i.e., segmentation) to correct crossbites and to add facial fullness
5. *Horizontal advancement* to improve midface projection and to open the upper airway
6. Bone *grafting of the zygomatic buttress* on the ipsilateral side to improve facial symmetry
7. Provision of access for *intranasal procedures* (e.g., septoplasty, inferior turbinate reduction, recontouring of the pyriform rims and the nasal floor).

Safe and effective first-stage Le Fort I osteotomies carried out during the mixed dentition are not practical as a result of the location of the developing teeth and the expected inhibition of any postoperative horizontal maxillary growth.

Osteodistraction Reconstruction of the Mandible during Childhood

Since 1992, DO has been used as a technique in an attempt to correct mandibular morphology in young patients with HFM.* In 2002, a literature overview was published by **Mommaerts and colleagues** to address the long-term results of early DO among patients with HFM.[148] It was concluded that no convincing evidence supported the benefits of DO over other techniques for the treatment of HFM, and DO was not found to offer advantages with regard to the limiting of complications. In 2009, **Nagy and colleagues** published a critical and exhaustive literature review in search of evidence of long-term stability after early distraction osteogenesis of the mandible in patients with HFM.[163] Eighty-nine relevant articles were reviewed. Only 13 studies were found to have sufficient scientific merit to be included. The authors concluded the following:

1. The majority of the studies reported unstable results after DO with regard to facial symmetry that especially affected ramus height.
2. Clinicians frequently hypothesized that the volume of the soft tissues of the affected side would increase after DO in patients with HFM. Interestingly, the only published study that used a volumetric evaluation showed no postsurgical improvement of the soft-tissue deficiency on the affected side after DO reconstruction.
3. Even after accepting the shortcomings of certain study designs and evaluation methods, none of the published studies demonstrated the convincing long-term stability of the mandibular dimensions after DO mandibular elongation.
4. Relapse in regeneration after DO was seen in the majority of the studies that used reliable evaluation methods.
5. Repeated DO was reported to be necessary when pursuing attempts to maintain facial symmetry during growth in the patient with HFM. Therefore, any gains in mandibular dimensions after early DO were not stable, whether as a result of relapse or growth impairment.
6. In published reports, most children with HFM were still rated as "unattractive" after surgery and showed no "improvement in self-esteem." Children with HFM have an elevated risk for childhood psychosocial difficulties.
7. If early DO is the treatment that is selected to be carried out during childhood for HFM, the patient

and family must accept that the procedure will have to be repeated later during the patient's life.

Costochondral Graft Reconstruction of the Mandible during Childhood

There are several basic theories regarding the mechanism of how mandibular growth occurs:

1. One theory of mandibular growth involves *chondroblastic proliferation* (i.e., cartilage formation with subsequent osseous replacement). Linear growth is primarily thought to be the result of condylar cartilage proliferation pushing the mandible forward and downward.
2. A second theory is the *functional matrix theory,* which explains mandibular growth primarily as a result of facial soft-tissue growth with subsequent projection (or pulling) of the mandible downward and forward in response to the forces of function. The condyle (and the condylar cartilage) is thought to merely secondarily react to the stimulating functional matrix forces that draw the mandible downward and forward. This is the theory behind the use of a Herbst appliance to "grow" a small mandible.
3. A third line of thinking is that both theories have merit. This explanation holds that a condylar growth center (i.e., chondroblastic proliferation) is present but that it is at least somewhat influenced by the physiologic function (i.e., functional matrix) of the mandible.

When the condyle and the components of the ascending ramus are hypoplastic or absent in patients with conditions such as HFM, surgeons have selected varied donor sources to replace the missing parts.* Autogenous replacements for the condyle have included 1) the metatarsal bones 2) the proximal head of the fibula 3) the costochondral junction of the rib (CCJ/rib) and 4) the sternoclavicular joint.

In general, the CCJ/rib bone is an expendable donor site and often an ideal morphologic contour match, with adequate strength at the mandibular recipient site. For these reasons, the CCJ/rib bone has been commonly used as a substitute for the "condylar growth center" and for the replacement of components of the ascending ramus. Unfortunately, in the skeletally immature patient, clinical observation after transplantation confirms unpredictable growth of the graft as compared with what would be considered "normal" growth or growth that is equivalent to the contralateral "normal" side of the mandible.

Clinical experience indicates that the CCJ/rib graft that is placed in the child or young teenager is prone to excessive growth. Although some would argue that overgrowth of the mandible and the need for additional surgical correction is a relatively minor consequence, experienced clinicians have found the secondary distortions in the maxillomandibular complex difficult to correct in a satisfactory way as compared with what could be achieved by single-stage reconstruction at the time of early skeletal maturity (Fig. 28-11). Unless pressing functional issues occur during childhood (e.g., obstructive sleep apnea), the advantages of a single-stage approach at jaw growth maturity to achieve favorable long-term function and aesthetic enhancement are difficult to ignore (Figs. 28-12 through 28-16).

Scientists began to focus on the biodynamics and growth of the transplanted CCJ/rib during the early 1990s. Researchers have addressed questions about differences in the biologic nature of the cartilage of the CCJ/rib; the epiphyseal growth plate; the mandibular condyle; and the sternoclavicular joint. It is now clear that the cartilage associated with the CCJ/rib and the epiphyseal plate of a long bone are derived from the primary cartilaginous template of the skeleton. These cartilages are relatively resistant to extrinsic competitive growth-related factors. Alternatively, the mandibular condyle and sternoclavicular cartilages arise from their own blastemas in association with the periosteum and then form as secondary cartilages.

Peltomaki and colleagues used a rat model to analyze the dynamic histology that occurred with the growth of the CCJ/rib.[183-192] The observed histologic findings are dependent on the amount of cartilage that remains on the autogenous CCJ at the time of transplant. One of the initial findings of these authors was that "costochondral grafts do not adapt to the new environment, but rather preserve their inherent growth potential." In subsequent studies, Peltomaki and colleagues continued to explore the idea of whether the intrinsic growth of the CCJ/rib may also be influenced by the interaction of hormonal factors and masticatory movements.[183-192] It is now clear that variations in mandibular growth after the use of a CCJ/rib graft in both humans and experimental animal model simulations likely vary in accordance with the amount of cartilage used in the graft.

Peltomaki notes that, in the CCJ/rib the distance from the bone cartilage junction to the germinative zone is approximately 0.4 mm to 0.5 mm. It is evident that the germinative cells will invariably be included in a CCJ/rib graft. It is also evident that, in clinical practice, considerable variation in the amount of germinative cells maintained will occur. The reported clinical differences in mandibular growth after the replacement of the condylar process with a CCJ/rib graft is likely the result of variations in the amount of cartilage included in each graft. Peltomaki believes that the number of germinative cells has a direct impact on rib elongation (i.e., overgrowth). Clinicians should be cognitive of the fact that the amount of cartilage included in the graft is of significance with respect to the

• **Figure 28-16** A newborn with a bilateral form of hemifacial microsomia that is more severe on the left side than the right and that involves the facial soft tissues and the jaws. The upper facial skeleton and the adnexal structures were essentially normal. The patient had an adequate airway and feeding ability at the time of birth and throughout childhood. At another institution when she was 7 years old, she underwent bilateral external distraction of the mandible. The procedure was unsuccessful for improving the mandibular dysmorphology or the occlusion. When she was 11 years of age, at another institution, the patient underwent a second mandibular distraction procedure with an internal device. This was also unsuccessful for improving the mandibular malformation or malocclusion. The patient had also undergone bilateral external ear reconstruction with a suboptimal result, and she wore external hearing aids. She presented to this surgeon when she was 15 years old with orthodontics in progress including 4 bicuspid extractions. She had a lifelong history of obstructed nasal breathing and deformities of the maxilla and the mandible. There was a marked Class II anterior open-bite malocclusion. An assessment was carried out that included an evaluation of the cervical spine, a complete computed tomography scan, and evaluation by a speech pathologist and an otolaryngologist. Reconstruction was executed and included septoplasty and inferior turbinate reduction; Le Fort I osteotomy (horizontal advancement, vertical adjustment, and counterclockwise rotation); bilateral ramus osteotomies (horizontal advancement and counterclockwise rotation) with interpositional grafting; and osseous genioplasty (vertical shortening and horizontal advancement). **A,** Facial views at 1 year of age, before any intervention. **B,** Facial views at 7 years of age, with bilateral mandibular distractors in place.

NOTE: In this patient with HFM, the lack of effectiveness of the two mandibular distraction procedures carried out in the mixed dentition is documented.

future growth of the reconstructed condyle–ramus unit. It is currently impossible to estimate the optimal amount of cartilage to be preserved in each individual case. Nevertheless, clinical and experimental studies support the notion that, by including only a "small amount" of cartilage in the CCJ/rib graft, less postoperative growth (i.e., overgrowth) can be expected.

Peltomaki examined the growth of the mandible after CCJ/rib graft condyle replacement in marmoset monkeys. Interestingly, in adult animals, the amount of cartilage did not make any difference with regard to the postoperative mandibular measurements. In the growing animal, a postoperative gradual deviation of the midline to the unoperated side occurred. The greater the amount of cartilage left in the graft at the time of transplantation, the greater the amount of midline deviation observed over time.

For a series of human patients, Peltomaki reviewed the histology of surgically removed overgrown CCJ/rib grafts that were initially placed during childhood. On the basis of the data, he believes that the unpredictable growth of the constructed condyle–ascending ramus is a common occurrence. Clinical and histologic examination revealed that the clinical type of overgrowth (i.e., linear versus exuberant) was not related to any specific microarchitecture, which in itself showed considerable variation. This suggested that other local factors (e.g., mandibular movement, loading of the reconstructed condyle) may also have an effect on the subsequent and eventual growth and overgrowth.

In general, for a first-stage mandibular procedure that is carried out during childhood to be considered successful in a patient with HFM, the growth of the reconstructed side of the mandible should equal or at least be close to that of the contralateral normal mandible. Unfortunately, despite decades of surgical experience with the use of the CCJ/rib graft as a reconstructive option for the missing condyle–ascending ramus in the growing patient with HFM, this option has not passed the test. Overgrowth is a frequent and serious consequence. The mechanism that causes this postsurgical growth disturbance is now clear. Predictable methods of overcoming this complication while still allowing the CCJ/rib graft to be effective have not been realized.

Osteodistraction of the Residual Mandibular Deformity after Costochondral Graft Placement during Childhood

Wan and colleagues reported their findings for the reconstruction of Type IIB and III mandibular malformations in patients with HFM.[279] Their basic approach was to reconstruct the ipsilateral mandible with a CCJ/rib graft (N = 30 grafts, 27 patients) during the mixed dentition (mean age, 9.9 years ± 4.1 years). As a result of a high failure rate, this was followed by DO treatment of the residual deficient mandible. CCJ/rib graft failure that required regrafting occurred in 7 out of 30 cases (23%). Undergrowth that required DO during the mixed dentition occurred in 17 cases (57%). Overgrowth with severe distortion that required surgical correction occurred in 3 of the 30 cases (10%). For the majority of study patients who later required CCJ/rib graft DO, the complication rate was exceedingly high. In addition, all study patients (N = 27) required definitive orthognathic surgery at growth maturity, despite earlier procedures having been carried out.

Corcoran and colleagues presented a series of 8 patients with HFM who underwent mixed dentition costochondral reconstruction and who then submitted to DO.[33] They found a 62.5% complication rate. Stelnicki and colleagues similarly reported on 9 patients who underwent mixed dentition CCJ/rib graft reconstruction and then required distraction.[252A] They reported a 33% rate of fibrous nonunion as well as other significant complications and limited ultimate success. On the basis of current published studies, it must be concluded that first-stage mandibular reconstruction with the use of CCJ/rib grafts during the mixed dentition for patients with Type IIB and Type III HFM deformities is fraught with complications and achieves limited success. *The theory that a mandible reconstructed in this way can be reliably "distracted' later if it does not grow normally has proved to be false.*

Facial Soft-Tissue Reconstruction

A variety of well-intentioned surgical attempts to correct the soft-tissue deficiencies of the *eyelid adnexal regions* in patients with HFM have been carried out. The transposition of a pedicled upper eyelid skin–muscle flap to the lower eyelid's deficient region is not technically difficult, but the resulting adnexal scarring inevitably results in an operated look that generally detracts from any positive advantages of the procedure. For this reason, it may be best for the patient and the family to consult an experienced pediatric oculoplastic surgeon when considering even minor eyelid surgical procedures for the patient with HFM. Decisions about the removal of epibulbar or bulbar dermoid cysts from the adnexal region are based on eye function and eyelid aesthetics.

The inferior displacement of the *lateral canthus* in a patient with HFM is a reflection of both orbital dystopia and hypoplasia of the lateral canthi and other components of the eyelid structures. Correction of the orbital dystopia through osteotomies and bone grafting and the completion of a direct lateral canthopexy are helpful and should be carried out when indicated, but these procedures will not fully correct hypoplasia of the lateral canthal complex.

When *temporal fossa* hollowing is clinically noticeable in the patient with HFM, it is a reflection of multilevel hypoplasia that may include that of the skin, the temporoparietal fascia, the temporalis muscle, and the squamous portion of the temporal bone. Attempts to fill the soft-tissue defect with local pericranial or temporoparietal flaps are generally not effective, because these tissues are part of the deficiency. The intrinsic hypoplasia of these flaps (i.e., of the temporoparietal fascia and the temporalis muscle) also explains why they have limited utility for adnexal region subcutaneous augmentation.

For many patients, the extent of soft-tissue hypoplasia in the *preauricular–cheek region* will be distinctly noticeable at conversational distance, even after effective skeletal reconstruction.[61,86,89,91,117,123,124,149,204,205,244,245,258,268,269] This results from multilevel hypoplasia of the subcutaneous tissue; the fat; the muscles of mastication and facial expression; and the parotid gland. For these patients, a well-designed soft-tissue "free" vascularized composite flap should be considered. When meticulously designed and expertly executed, the transfer of soft-tissue flaps from other body regions (with microvascular reanastomosis) may be the alternative of choice. Parascapular free flaps have become the workhorse for the reestablishment of facial soft-tissue volume since this process was first described by Dos Santos.[40] Siebert and colleagues found that the parascapular flap allows for the reasonable correction of contour defects and yields improved facial aesthetic results in selected patients with HMF while minimizing scarring by providing vascularized soft tissue in the subcutaneous plane.[244,245] Fortunately, hypoplasia of the centrally located soft tissues of the face (i.e., the nose, the medial aspects of the upper and lower lips, and the submental region) is not seen in patients with HFM. The soft-tissue reconstruction requires an experienced microvascular surgeon working closely with a maxillofacial and a auricular surgeon to coordinate the flap inset; to minimize recipient-site morbidity; and to coordinate

skeletal and soft-tissue reconstruction. The timing of soft-tissue preauricular–cheek region reconstruction is generally planned to follow the skeletal reconstruction.

Advocates of the DO technique for mandibular reconstruction in patients with HFM had hoped that the soft tissues (i.e., the skin, subcutaneous tissue, and muscle) would increase in bulk when this method is used. However, this hoped-for advantage has not been documented by clinical studies. Of importance is that effective skeletal reconstruction by whatever means will favorably influence the aesthetic appearance of the soft-tissue envelope; however, it will not directly increase the soft-tissue volume.

Dermal fat grafts, *autogenous fat injections,* and other forms of soft-tissue augmentation have gained in popularity. The results of autogenous fat injection are variable and considered technique sensitive, but are generally not harmful and clearly promising. **Tanna and colleagues** investigated the use of serial autologous fat grafting to restore soft-tissue contour in patients with HFM.[259] Patients with moderate to severe HFM were divided into two groups. Group I included those who were undergoing microvascular free-flap reconstruction (i.e., inframammary extended circumflex scapular flaps, n = 10). Group II included patients who were undergoing multiple staged autogenous fat grafting (n = 21). The two patient groups had similar OMENS scores (2.4 and 2.3, respectively) and similar pre-reconstruction facial symmetry scores (74% and 75%, respectively). During the final evaluation, facial symmetry scores were 121% for the microvascular free-flap group and 99% for the fat-grafting group. Furthermore, no statistically significant difference between the microvascular and fat graft groups with regard to either patient or physician rating of overall satisfaction was noted.[67,107,259]

External Ear Reconstruction

In the hands of a few experts, surgical reconstruction of the external ear can be satisfactorily achieved with a staged approach.[8,10-15,54,260,261] The methods described by Brent continue to represent the reference standard for auricular reconstruction.[10-15] The successful placement of a well-sculpted autogenous cartilage framework is the foundation for a sound auricle repair. Brent prefers to wait until the patient is at least 6 years old, when rib cartilage is adequate for the reconstruction in most children. The synchondrotic region of the sixth and seventh ribs will then provide an ample cartilage block to use to form a framework for the ear. With the use of a prefabricated template of the contralateral ear and preoperatively determined measurements of the face, the ear's position and size are chosen, and a small preauricular incision is made. Other stages of auricular construction include lobule transposition, the detachment of the ear with a skin graft, hairline management, and tragus construction. Other options for external ear reconstruction include the use of alloplastic and homologous frameworks. Alloplastic materials currently in use include silicone or Medpor (Porex Surgical, Inc, College Park, Ga). These foreign substances are more susceptible to infection, soft-tissue wound dehiscence, and minor trauma, even decades after reconstruction. Techniques of tissue engineering with bovine cartilage cells continue to be tested; these cells can be grown in the laboratory and seeded on a synthetic biodegradable ear template that is then implanted beneath the skin of an immunocompetent mouse. Unfortunately, until tissue engineering evolves beyond the currently encountered immunogenic problems, sculpted autogenous rib cartilage will remain the material of choice for the surgical repair of the ear.

Before completing microtia reconstruction, a decision must be made about whether middle-ear surgery will eventually be carried out. Auricular construction should precede any middle-ear surgery; after an atretic ear canal is opened, the chances of obtaining a satisfactory auricular reconstruction are severely compromised as a result of scarring of the soft-tissue envelope. Consideration should also be given to the need for condyle-ascending ramus reconstruction (i.e. Type IIB and Type III malformations). If CCJ/rib graft harvesting will also be required then the location of each donor site becomes even more important.

External Auditory Canal and Middle-Ear Reconstruction

Occasionally, neurosensory hearing loss is present in the patient with HFM, but hearing loss is generally attributable to external auditory canal stenosis or atresia, hypoplasia of the middle-ear cavity, or ankylotic or missing ossicles.[17,18,223,280] Ankylotic or non-functioning ossicles limit hearing conduction to the same extent that would occur if the ossicles were absent. Generally, attempts to reconstruct the external auditory canal and the bones of the middle ear for patients with HFM are not carried out. As long as adequate hearing is present in the contralateral ear, clinical problems generally relate only to the patient's ability to locate the origin of the sound. For most patients, attempts to restore middle-ear function involve residual conductive hearing loss to the extent that "stereo" hearing is rarely achieved.

Bone-Anchored Hearing Aid Option

A *bone-anchored hearing aid* (BAHA) consists of a permanent titanium fixture that is surgically implanted into the skull bone behind the ear and a small detachable sound processor that clips onto the fixture. BAHAs are suitable for people with conductive or mixed hearing loss who cannot adequately benefit from or who prefer not to use conventional hearing aids.

Colquitt and colleagues completed a systematic review and economic evaluation of BAHAs for people who are bilaterally deaf. [29] Previous prospective studies of adults or children with bilateral hearing loss were eligible for review. Twelve studies were included; there were seven cohort

pre-post studies and five cross-sectional audiologic comparison studies. Comparisons were made between BAHAs and the following: 1) conventional hearing aids, which are also known as air-conduction hearing aids (ACHAs) 2) bone-conduction hearing aids (BCHAs) and 3) unaided hearing and ear surgery. The study also looked at 4) unilateral versus bilateral BAHAs. Outcomes reviewed included hearing measures, validated measures of quality of life, adverse events, and measures of cost-effectiveness.

There appeared to be some audiologic benefits of BAHAs for this group of patients including 1) improvements in speech as compared with BCHAs and 2) understanding and noise as compared with ACHAs (however, ACHAs may produce better audiologic results for other outcomes). In addition, 3) hearing was found to be improved with the use of BAHAs as compared with unaided hearing and 4) studies that compared unilateral with bilateral BAHAs suggested the benefits of bilateral BAHAs in many situations.

However, prospective case series of BAHAs reported rates of 6.1% to 19.4% for the loss of the implants over time. In addition, the financial analysis suggests that BAHAs may not be a cost-effective option in terms of hearing gain and probability of needing alternative aids. Interestingly, the greater the benefit to the individual from aided hearing and the greater the difference in the proportion of people using the hearing aid for more than 8 hours per day, the more likely the BAHAs were a cost-effective option.

Janssen and colleagues completed a systematic review of bilateral BAHAs for bilateral permanent conductive hearing loss.[88] This was a review of the literature from between 1977 and 2011, and it included studies in which subjects of any age had permanent conductive hearing loss and bilateral implanted BAHAs. Eleven studies met the criteria for data analysis. Bilateral BAHAs were found to provide audiologic benefit as compared with unilateral BAHAs (i.e., improved thresholds for tones, speech in quiet and in noise, improved localization/lateralization, and patient's perceived subjective benefit). Disadvantages of bilateral BAHAs included 1) listening in noise in some condition 2) presumed additional cost and 3) presumed increasing adverse event risk. The authors concluded that bilateral BAHAs provided additional objective and subjective benefit as compared with unilateral BAHAs.

Conclusions

Hemifacial Microsomia generally occurs sporadically and without a familial pattern. It is characterized by variable deficiencies of the skeletal and soft-tissue structures within the nasal placode and the first and second branchial arches, primarily on one side. Considerations during infancy and early childhood center on airway, feeding, hearing, vision, and the need for psychosocial family support. The degree of malformation present at the time of birth in the patient with HFM is believed to be relatively stable and non-progressive with age.

The current approach to the correction of the malformations associated with HFM is to stage the reconstruction to coincide with facial growth patterns, visceral functions, and psychosocial development. A precise morphologic analysis of each patient's anomalies followed by a broad-based reconstructive plan serves to clarify for the clinicians and the family the objectives of each stage and method of treatment. As we continue to define our rationale for the timing, methods, and extent of interventions and then to objectively evaluate the functional, morphologic, and psychosocial outcomes, we will improve the outlook for individuals who are affected by HFM.

Binder Syndrome: Evaluation and Treatment

JEFFREY C. POSNICK, DMD, MD

- Current Approach to Reconstruction
- Skeletal Stability after Orthognathic Reconstruction
- Controversies and Unresolved Issues
- Conclusions

In 1939, Noyes first described a patient whose face was characterized by a flat nasal tip and a retruded maxillary–nasal base.[32] He did not recognize this as an entity unique from other known forms of maxillary retrusion. It was not until 1962 that von Binder came to recognize the specific entity of nasomaxillary hypoplasia that is now called *Binder syndrome.*[53] He described physical findings of nasomaxillary hypoplasia, a convex lip, a vertical (short) nose, a flat frontonasal angle, an absent anterior nasal spine, limited nasal mucosa, and hypoplastic frontal sinuses. von Binder postulated that the hypoplasia was the result of a disturbance of the prosencephalic induction center at a critical phase during development. In 1989, Sheffield and colleagues reviewed 103 cases of chondrodysplasia punctata (CDP) seen in Melbourne, Australia, over a 20-year period.[48] They concluded that Binder syndrome should be classified as a mild form of CDP. In 1991, Sheffield and colleagues pointed out that most patients with Binder syndrome seek medical attention during adolescence.[47] By this age, the confirmatory diagnostic radiologic features of CDP have disappeared, so the diagnosis of CDP is often not considered. Older patients may show terminal phalangeal hypoplasia of the hand and variable anomalies of the vertebrae (i.e., vertebral clefting). Associated malformations of the cervical spine primarily affect the atlas and the axis without known clinical sequelae.[35,43] Familial recurrence has been reported, and inheritance may occur as an autosomal recessive trait with incomplete penetrance.[34] The syndrome may also be of a threshold character with a genetically multifactorial background.[5,14,45]

The physical findings of Binder syndrome result from hypoplasia of the anterior nasal floor (fossa praenasalis), and the anterior maxilla including the pyriform rim region.[26,33] When viewing the nose–upper lip complex from the worm's-eye perspective, typical variations from normal are described as a retracted columella–lip junction, a lack of normal triangular flare at the nasal base, a perpendicular alar–cheek junction, a convex flat nasal tip with a wide and shallow philtrum, crescent-shaped nostrils without a distinct sill, and a stretched and shallow cupid's bow.[27,41] Striking profile characteristics of the nose include vertical shortening of the columella, a lack of tip projection, perialar flattening, and an acute nasolabial angle.[11,28] The dentition and occlusion in an untreated individual will typically demonstrate the proclination of the maxillary incisors, "peg" laterals, and a canine Angle class III negative overjet tendency.[21]

Anthropometric explanations for these findings were first suggested by Zuckerkandl in 1882, when he described an anomaly in the anterior nasal floor in which the normal crest that separates the nasal floor from the anterior surface of the maxilla was absent.[56] Instead, a small pit—the fossa praenasalis—constituted the pyriform aperture.[18,24] Other investigators have pointed out that the premaxilla of normal Caucasian individuals is incorporated into the upper arch.[2,3] This results in a prominence or projection of the base of the nose. By contrast, when the premaxilla (i.e., the primary palate) is not incorporated into the arch (i.e., in higher primates, certain racial groups, persons with Binder syndrome, and individuals with bilateral clefted alveolar ridges and lips), there will be flattening of the premaxillary region and of the base of the nose.[6] This is more commonly seen among African and Asian people.[10]

In an attempt to reconstruct the skeletal deformities associated with Binder syndrome, clinicians have suggested a spectrum of procedures, including Le Fort I osteotomy, Le Fort II osteotomy, Le Fort III osteotomy, and a combination of Le Fort I and II osteotomies.[4,8,12,17,19,20,22,23,31,36,39,42,44,49,51,55] Augmentation of the infraorbital rims, the pyriform rims (paranasal), and the anterior maxilla with the use of a spectrum of materials have all been tried.[7,25,40,50] Suggested nasal reconstructive

options have included autogenous, homogenous, and allogenic bone and cartilage grafts that extend up the columella (i.e., from the base of the maxilla to the nasal tip) and over the nasal dorsum (i.e., from the radix to the tip).[1,9,13,15,19,29,30,38,39,46,52] Suggested soft-tissue procedures include septal cartilage and mucosal flaps, upper lip to nasal skin flaps to lengthen the columella, and a variety of subcutaneous augmentation procedures and fillers.[37,54] Compensating orthodontic or dental restorative work may also be undertaken.

With Binder syndrome, a degree of hypoplasia of the premaxilla and of the quadrangular cartilage of the nasal septum is a consistent finding. This author agrees with Holmstrom and colleagues that, with this anomaly, there is a local shortage of bone in the premaxillary region and an absence of cartilage in the anterior septum.[18-20] However, as Tessier pointed out, there is no significant shortage of soft tissue available.[50-51] Furthermore, modification of the uninvolved orbits, zygomas, and upper nasal dorsum (i.e., the nasal bones) is rarely indicated or advantageous. The observed facial features in an individual with Binder syndrome are dependent on the degree of hypoplasia of the anterior nasal floor (fossa paranasalis) present at the time of birth. The deformities are believed to be non-progressive with age.

Current Approach to Reconstruction

The approach to the correction of the Binder syndrome deformity is to plan for a staged reconstruction to coincide with facial and dental growth patterns and psychosocial needs.[16,39] An analysis of each patient's morphology is followed by a review of the reconstructive options with the patient and family. The most gratifying long-term functions (i.e., occlusion and breathing) and facial aesthetics are generally achieved when carrying out the reconstruction after the completion of growth and before the individual's graduation from high school (Fig. 29-1 through 29-5). Orthodontic treatment should be coordinated with consideration of orthognathic correction and premaxillary augmentation to be followed by definitive nasal reconstruction. The ideal orthodontic treatment often includes maxillary first bicuspid extractions with retraction and alignment of the anterior teeth to produce ideal incisor inclination within solid basal bone. Unfortunately, many individuals with Binder syndrome will have already been treated with an orthodontic camouflage approach. During the process, the maxillary incisors are tipped facially, and the mandibular incisors are often retroclined. This will typically achieve successful neutralization of the occlusion (i.e., the correction of overjet), but it will leave the patient looking as if he or she has a maxillary deficiency. Attempts at surgical augmentation after orthodontic camouflage are generally suboptimal. When indicated, definitive orthognathic reconstruction is planned to idealize the vertical, transverse, and horizontal midface proportions. A Le Fort I osteotomy (horizontal advancement and a variable degree of vertical lengthening) is frequently combined with an osseous genioplasty (vertical shortening and horizontal advancement). Sagittal split ramus osteotomies are often needed to avoid the limitations inherent to mandibular autorotation. Further reconstruction involves the application of a crafted bone graft to the deficient premaxillary and pyriform rim regions. This is best accomplished simultaneously with the orthognathic procedures.

Text continued on p. 1177

• **Figure 29-1** A 17-year-old boy, who was born with Binder syndrome was referred by his orthodontist for surgical evaluation. When he was 7 years old he underwent nasal augmentation with Silastic implants with another surgeon. Orthodontic treatment including maxillary first-bicuspid extractions and orthognathic and nasal surgery was chosen. The patient's procedures included a Le Fort I osteotomy (horizontal advancement); the removal of nasal implants; osseous genioplasty (horizontal advancement); and nasal reconstruction (corticocancellous iliac graft). **A,** Facial views at 10 years old with Silastic implants in place.

Ideally, the nasal reconstruction is carried out after the orthognathic and anterior maxillary augmentation procedures (see Fig. 1-5).[38,39] This is accomplished by reconstructing the cartilaginous nasal deficiency. Stretching of the soft-tissue envelope over the reconstructed underlying nasal cartilage framework is accomplished at wound closure. When first-stage early nasal augmentation was carried out during childhood and before orthognathic correction, some profile improvements maybe achieved, but a relief of the stigma of Binder syndrome is not likely. Early nasal augmentation also imposes limitations on the child's physical activity to prevent graft fracture or displacement. These restrictions on the daily activities of childhood are likely to be more psychosocially traumatic than the original nasal deformity. For effective reconstruction, all aspects of the deformity should be addressed with a coordinated long-term approach in mind.

Skeletal Stability after Orthognathic Reconstruction

Few authors have looked at the early or late skeletal stability achieved when osteotomies are carried out to correct the Binder syndrome midface deficiency. In a previously published study, Posnick and colleagues prospectively assessed initial and long-term skeletal stability after orthognathic reconstruction including a Le Fort I osteotomy followed by nasal reconstruction in a consecutive series of skeletally mature Caucasian individuals born with Binder syndrome.[39]

Patients and Methods

The medical and cephalometric records and late posttreatment (surgical and orthodontic) clinical examination of a consecutive series of patients with Binder syndrome (n = 7) who underwent Le Fort I osteotomy by a single surgeon (Posnick) during a 6-year period were reviewed. The patients' ages at operation ranged from 16 to 20 years (mean, 17 years). For all study patients, the prospective protocol required obtaining a lateral cephalogram preoperatively, immediately (i.e., 3 to 7 days) after surgery, 6 to 8 weeks after surgery, and 1 year after surgery. At the time of final review, all patients had obtained their interval cephalograms and were available for a final clinical evaluation.

All patients underwent orthodontic treatment, orthognathic surgery, and nasal reconstruction. During the initial evaluation, all study patients were judged to have inadequate alveolar bone to retain the full complement of maxillary teeth and to maintain long-term periodontal health. Extraction of maxillary first bicuspids was carried out to remove dental compensations and to establish normal dentoalveolar arch form and incisor inclination. All patients underwent a standard one-piece Le Fort I osteotomy extended through the zygomatic buttress (below the malar eminence) and anteriorly through the hypoplastic pyriform aperture. All grafts to the upper jaw (five of seven patients) were autogenous corticocancellous iliac bone. After the titanium plates and screws were in place to stabilize the osteotomy, corticocancellous bone grafts were crafted to reconstruct the area of hypoplasia of the premaxilla. The grafts were fixed with additional plates and screws. Simultaneous sagittal split ramus mandibular osteotomies were carried out in three of seven patients. The majority of patients (six of seven patients) also underwent osseous genioplasty with horizontal advancement and varying degrees of vertical shortening. Six of seven patients underwent autogenous grafting of the nose (costochondral grafts in four patients, a cranial graft in one patient, and an iliac graft in one patient). One patient underwent a coronal scalp incision, the others (five of six patients) underwent an open rhinoplasty (i.e., columella skin-splitting incision) approach. Only one of the seven patients underwent simultaneous orthognathic surgery and nasal reconstruction.

Results

The serial cephalometric radiographs for each patient were analyzed, and the preoperative and immediate postoperative tracings were superimposed. The end result was a Cartesian coordinate system that illustrated the horizontal and vertical directional changes of the maxilla at intervals after surgery. In addition, the incisor overjet and overbite measurements from the 1-year postoperative cephalogram were documented and compared with the measurements taken at the final clinical assessment. All patients had a complete set of longitudinal clinical and cephalometric records, and all were available for late postoperative clinical reassessment at the close of the study. Clinical follow-up ranged from 1.5 to 5.5 years (mean, 3 years) at the completion of the study.

Perioperative morbidity was unremarkable when patients were reviewed for cardiopulmonary compromise, maxillofacial infection, hemorrhage, aseptic necrosis, loss of teeth, and need for root canal therapy. All patients maintained a positive overjet and overbite at the incisors as documented on the 1-year postoperative clinical and cephalometric examinations. The mean effective maxillary advancement achieved was 6.0 mm, with 5.9 mm maintained 1 year later. The mean anterior vertical change of the maxilla was 4.2 mm immediately after the operation and 3.1 mm after 1 year. The mean posterior vertical change of the maxilla was 2.8 mm immediately after the operation and 2.2 mm after 1 year. In review, the fixed and grafted Le Fort I osteotomies were able to maintain the horizontal advancement. Although a degree of anterior vertical relapse occurred, the long-term maintenance of satisfactory occlusion with a positive overjet and overbite was documented in all patients.

Controversies and Unresolved Issues

The precise genetic cause of Binder syndrome has not yet been confirmed. Gorlin and colleagues suggested that maxillonasal dysplasia was a non-specific abnormality

of the nasomaxillary complex.[14] Over time, it has become apparent that many patients with Binder syndrome ultimately have a form of chondrodysplasia punctate, although genetic heterogeneity exists. Children with the X-linked recessive for of chondrodysplasia punctate have molecular alterations in the arylsulfatase E gene. Because of the X-linked inheritance pattern, females with this form of chondrodysplasia punctate tend to be much more mildly affected than males. Molecular testing for alterations in arylsulfatase E is clinically available and should be tested for.

In retrospect, the features defined by von Binder were not altogether typical of those found in most patients who are currently categorized as having Binder syndrome. It is also known that frequent ethnic characteristics of both Asian and African individuals are a sloped backward and vertically short anterior maxilla, pyriform rims, and a deficient dorsum of the nose. This results in deficiency of alveolar bone to house the maxillary incisors. The anterior nasal spine is hypoplastic, but it is often present as a small ridge. A lack of height of the dorsum of the nose (i.e., bone and cartilage) with increased width is a frequent ethnic characteristic of Asian and African individuals but not a finding among patients with Binder syndrome. We believe that many patients who are believed to have Binder syndrome more accurately represent ethnic variation. This may well encompass many of the Asian patients described and treated by Goh and Chen in their review of nasal reconstruction for Binder syndrome.[13]

Holmstrom and others support an orthognathic approach and state that, in a series of Caucasian patients with Binder syndrome (54% of the study group), a majority "suffered a class III malocclusion."[18-20] Although an edge-to-edge incisor relationship may be possible with orthodontics only, it is generally accomplished with excessive maxillary incisor proclination. This camouflage approach does not address the flat midface appearance or the long-term orthodontic retention needs, and it may lead to periodontal sequelae. To correct the maxillary incisor inclination, an alveolar space analysis will confirm the advantage of extracting maxillary first bicuspids in many of these patients. With molar anchorage, the orthodontist is able to retract the anterior teeth into the space created by the bicuspid extractions, and ideal incisor positioning is accomplished. This approach will further unmask the maxillary hypoplasia and allow for an effective horizontal advancement at the Le Fort I level. When this is combined with a premaxillary region crafted bone graft reconstruction, maximum improvement in the perialar and nasal base morphology is also accomplished. An orthodontic camouflage approach should only be carried out with full disclosure to the patient and his or her family.

The aesthetic advantage of a vertical reduction and an advancement osseous genioplasty in the majority of individuals with Binder syndrome likely reflects the longstanding mouth-breathing pattern and its effects on anterior mandibular growth. In three of the seven patients in the study by Posnick and colleagues, bilateral sagittal split osteotomies were also necessary to correct the secondary mandibular dysmorphology or to prevent the inherent shortcomings of mandibular autorotation.[39] In none of the patients was the mandible "set back" as a camouflage for maxillary deficiency.[39]

Binder syndrome is not an orbital, zygomatic, nasal bone, or cranial vault malformation. Over time, it has been found that alteration of these regions is counterproductive. A Le Fort III osteotomy would have the disadvantage of flattening the nasofrontal angle, producing enophthalmos, and resulting in distortions (step-offs) of the lateral orbital rims. A Le Fort II osteotomy would also flatten the nasofrontal angle, produce enophthalmos, and result in distortions (step-offs) along the infraorbital rims. In addition, neither procedure would directly address the nasal septal cartilaginous vault malformation nor address the deficient premaxillary region.

In my experience, corticocancellous iliac bone offers a preferred volume, quality, and osteogenic potential to reconstruct the anterior alveolus–floor of the nose–anterior nasal spine region. Full-thickness cranial bone may lack the necessary volume (thickness) for premaxillary construction. The use of a rib graft is likely to be inadequate in both volume and quality. When the nasal reconstruction follows within 6 months after grafting and the new (bone-grafted) premaxilla is used as a platform, less resorption is expected. The use of artificial materials in this region circumvents the issue of resorption and donor-site morbidity, but the long-term concern of recipient-site infection and extrusion must be considered.

Effective facial rehabilitation for the patient with Binder syndrome must address the nasal deformity. Potential pitfalls to the nasal reconstruction merit discussion. The open rhinoplasty technique (i.e., the columella splitting incision) allows ideal access to the area of the nose that requires reconstruction. Whenever possible, the surgeon should avoid other external nasal incisions carried out either for exposure (e.g., coronal scalp flap, vertical incisions directly over the nose) or in an attempt to directly lengthen the columella (e.g., Cronin technique). In the Caucasian patient, if a graft is placed from the radix to the nasal tip, a technical error will be made unless the surgeon first reduces (i.e., burs down) the bony dorsum from the frontonasal suture to the caudal aspects of the nasal bones before the augmentation procedure. If this is not done, flattening of the nasofrontal angle occurs, and an unnatural facial appearance will result. Achieving a flexible (or at least "nonfirm") reconstructed nasal tip is preferred. A relatively soft nasal tip with enough strength for tip projection is best accomplished with the use of a rib cartilage graft. The lower lateral cartilages are sutured over the top of the graft. If a full-length dorsal bone graft is required (i.e., from the radix to the tip), then stable fixation is necessary; this may be accomplished in a number of ways (e.g., plates and screws, lag screws, Kirschner wires [K-wires]), depending on the clinical circumstances. Placing a protective external

nasal splint over the grafted region limits swelling and assists with immobilization and overall healing. If dorsal bone augmentation is carried out, union to the underlying nasal bones is essential to achieve long-term facial aesthetic and functional objectives.

Holmstrom reviewed the long-term results of nasal reconstruction in a series of patients with Binder syndrome and found overall good results with a variety of techniques.[18-20] A review of nasal reconstruction options is listed below. The option selected for a specific patient is dependent on the unique presenting dysmorphology, the potential risks, the patient-specific objectives, and the surgeon's comfort level with the particular technique.

1. A cranial graft placed through a coronal scalp incision offers ideal access to the nasofrontal region for contouring and graft stabilization (i.e., plates and screws), and it provides excellent bone volume and quality. The lower lateral cartilage is then sutured over the graft at the tip via a columella incision. This approach generally requires craniotomy and a full-thickness graft, depending on the volume of bone required. Unfortunately, it results in a firm nasal tip that has a tendency toward a degree of resorption and that is prone to fracture with trauma. This approach is preferred only for the occasional patient in whom significant reconstruction of the nasofrontal region and augmentation of the bony dorsum is required (see Fig. 29-5).
2. A costochondral (bone and cartilage) graft maybe placed through a columella splitting incision. This results in a relatively "non-firm" nasal tip with limited resorption or risk of warping over time. If the relatively thin and malleable rib graft is placed in a cantilever fashion (i.e., without a columella strut for stabilization), there is a tendency for non-union with the underlying nasal bones and dislocation or fracture after minimal trauma. If the graft extends from the radix, it may also flatten the nasofrontal angle in an unfavorable way. This approach is generally not a first choice (see Fig. 29-1).
3. If a costochondral graft is selected for dorsal reconstruction (as described previously), a separate columella (rib cartilage) strut graft maybe crafted and then secured with sutures to the dorsal costochondral graft at the new nasal tip. Temporary stabilization of the dorsal bone graft component may be accomplished with a transcutaneous K-wire. A second short buried K-wire is placed to stabilize the rib cartilage (caudal strut) at the base of the maxilla (see Fig. 29-2).
4. An anterior iliac (corticocancellous) graft offers another option, but this is only used when extensive bone volume reconstruction is required. It is placed as a crafted L-shaped strut that is stabilized at the base of the premaxilla with titanium plates and screws and over the mid dorsum with percutaneous K-wires. When iliac bone is used at the time of the Le Fort I osteotomy for augmentation of the premaxilla, additional graft may be harvested for simultaneous nasal reconstruction, as described previously. This surgeon has used this combined single-stage approach only in unique and specific circumstances, because very few deformities require upper dorsal reconstruction (see Fig. 29-1). This approach also raises the level of complexity of the procedure by involving the need for sophisticated intraoperative airway management.
5. An L-shaped rib cartilage graft reconstruction has become this author's preference whenever the Binder deformity allows. With this procedure, it is not necessary to harvest the L-shaped rib cartilage graft in one piece. Rather, two struts (dorsal and columella) are crafted separately and then inset and sutured together to form the new nasal tip. The columella strut graft extends from the base of the maxilla to the nasal tip. It is fixed in place at the base of the maxilla with a buried K-wire (no. 32 threaded) to prevent slippage or movement. The dorsal strut graft extends from the caudal edge of the nasal bones to the new nasal tip, where it is secured to the columella strut graft with the use of non-resorbable suture material. Warping of the cartilage graft can occur, but resorption is not a problem. A separate K-wire (no. 32 threaded) may be inserted through the spine of the dorsal graft before inset to limit the risk of warping. The lower lateral cartilages are sutured over the top of the grafts, and the end result is a flexible nasal tip. This rib cartilage reconstruction option is preferred whenever feasible (see Chapter 34).

For the individual with Binder syndrome, early reconstruction of the dysmorphic nose (i.e., between the ages of 5 and 12 years) to improve tip projection and to encourage self-esteem is technically possible, but the surgeon should proceed with caution. Disadvantages include the need for additional nasal procedures at the completion of growth and after definitive jaw reconstruction. The inherent perioperative risks and expense; the creation of scar tissue within the nasal soft-tissue envelope; and the need for the child to avoid normal school-aged physical activities to prevent graft dislodgement or fracture should also be considered (see Fig. 29-1, *A*).

Conclusions

The individual with Binder syndrome presents with hypoplasia of the anterior maxilla and the caudal aspect of the cartilaginous nose. No genetic marker yet exists for this condition, and diagnostic confusion with normal ethnic variations of premaxillary and nasal anatomy is frequent. A staged reconstructive approach is generally carried out during the teenage years, before the patient graduates from high school. In Caucasian patients, this often includes orthodontic treatment, orthognathic procedures, anterior

maxillary augmentation, and nasal reconstruction. The orthodontic treatment relieves dental compensation and often includes maxillary first bicuspid extractions. Orthognathic surgery includes a Le Fort I osteotomy to idealize any vertical, transverse, or horizontal facial disproportions with simultaneous augmentation of the deficient premaxillary region. An osseous genioplasty further improves profile aesthetics. Nasal reconstruction (often with autogenous rib cartilage) follows orthognathic surgery to project the nasal tip and to stretch the overlying soft-tissue envelope.

General Considerations

Craniosynostosis, which is the premature fusion of cranial sutures, affects approximately 1 in 2500 children. Patients may present with a wide range of phenotypic and functional deformities.[94] Virchow's law from 1851 states that the premature fusion of a cranial vault suture results in growth arrest perpendicular to the affected suture and compensatory growth parallel to the fused suture.[16,164,269] This principle is generally applicable to single sutures; multisutural synostosis—such as the combination of sagittal and lambdoid synostosis (coup de sabre) or a cloverleaf skull—can assume more complex patterns of cranial morphology.[43,46,47] In addition to the type of affected suture, the eventual head shape depends on the timing and order of cranial suture fusion. Craniosynostosis may be of prenatal or perinatal onset, or it may occur during infancy.[14,74] The earlier synostosis occurs, the more dramatic the effect on subsequent cranial growth and development; the later synostosis occurs, the less effect on cranial growth and development.[44]

Active pediatric neurosurgical services generally see a characteristic frequency, gender predilection, and phenotypic presentation for sutural involvement.[6,15,55,125,133,154,161,193,232,238,243,278,283] Sagittal synostosis occurs most commonly, with a higher incidence among boys than girls. Patients typically present with a boat-shaped skull (i.e., scaphocephaly) in combination with midline ridging in the posterior half of the skull. Metopic synostosis is currently the second most frequent form of synostosis. Presentations occur along a spectrum that ranges from metopic ridging to the presence of a triangular-shaped skull (i.e., trigonocephaly). It should be noted that metopic ridging is common during infancy and childhood and that it is not necessarily associated with a diagnosis of craniosynostosis. Coronal synostosis occurs next most frequently; girls slightly predominate or, in some surveys, boys and girls have equivalent frequency.[46] Unicoronal synostosis is marked by frontal plagiocephaly, whereas bicoronal synostosis is characterized by a short and wide skull (i.e., brachycephaly). Multiple synostoses of various types are less common than coronal synostosis. Lambdoid synostosis occurs with least frequency, and it is marked by occipital plagiocephaly.[44]

Craniosynostosis is etiologically heterogeneous and pathogenetically variable. Overall, 8% of cases have a familial component, and this is generally marked by an autosomal dominant inheritance pattern. Specifically, pedigrees are familial in 14.4%, 6%, and 5.6% of coronal, sagittal, and metopic synostoses, respectively.[44] Although some pedigrees show synostosis of a specific suture, others may show fusion of different sutures in affected relatives of the same family. Different chromosomal aberrations have been linked to craniosynostosis, with variable penetrance. In some conditions the penetrance is high, such as with dup(3q), del(7p), del(9p), and del(11q). In other cases, penetrance

can be very low, such as with dup(5p), del(6)(22q22.2-q23.1), del(8q), and dup(15q).[44]

Many syndromes are associated with craniosynostosis, and well over 100 are known.[44] It is important to accurately diagnose syndromal patients for three reasons.[22] First, most syndromes with craniosynostosis affect not only the cranial vault but also the cranial base and the midface. Deficiencies in these skeletal sites, which are variable in degree yet commonly serious, must be addressed as part of the staged reconstructive approach. Second, syndromes are often genetic and familial, thus necessitating proper counseling. Third, depending on the experience of the particular surgeon, the molecular diagnosis should be made. Often, the patient may be referred for molecular diagnosis and counseling to avoid the possibility of litigation.[37,43,46,47]

Primary forms of craniosynostosis are most common and include single- and multi-sutural synostosis. Some conditions, however, result in secondary synostosis. These include hyperthyroidism; rickets; mucopolysaccharidoses, such as Hurler syndrome and Morquio syndrome; hematologic disorders, such as thalassemia and sickle cell anemia; teratogens, such as diphenylhydantoin, retinoids, valproate, and aminopterin; and certain malformations, such as holoprosencephaly and microcephaly.[44]

Mutations in Craniosynostosis and Craniosynostosis Syndromes

Mutations responsible for craniosynostosis have been identified in *FGFR1*, *FGFR2*, *FGFR3*, *TWIST*, *MSX2*, *EFNB1*, *RAB23, EFNA4*, *POR*, and *ALPL*.[44] These include Apert syndrome (two common *FGFR2* mutations; Ser252Trp, Pro253Arg), Crouzon syndrome (more than 30 *FGFR2* mutations), Pfeiffer syndrome (more than 30 *FGFR2* mutations), are known and at least 6 of them are the same as those found with Crouzon syndrome; one Pfeiffer syndrome (mutation on *FGFR1*).* In addition, there are some cases of *FGFR2* mutations with isolated coronal synostosis as well as with some other forms of non-syndromic synostosis. A single known *FGFR2* mutation is known for Jackson-Weiss syndrome.[1,41,182] Although this disorder is distinctly uncommon, affected families are often large, with variable phenotypic expression. Beare-Stevenson cutis gyrate syndrome involves one of two possible mutations in the transmembrane domain of *FGFR2*.[37,42]

Muenke syndrome is the most common craniosynostosis syndrome that is currently known. It involves a single mutation on *FGFR3,* and it is characterized most commonly by unilateral coronal synostosis and less commonly by bicoronal synostosis. About 6% of affected patients have macrocephaly without synostosis, and cloverleaf skull has been reported in some instances.[37,42] Therefore, all patients with coronal synostosis should be tested for this very common *FGFR3* mutation; if they are negative, they should be tested for *FGFR2.*

Crouzonodermoskeletal syndrome is characterized by one specific *FGFR3* mutation. The name indicates its characteristic features: either a Crouzonoid or cloverleaf skull appearance; acanthosis nigricans; and a decreased interpediculate distance that is radiographically present but not clinically significant. Serious decreased interpediculate distance is a feature of the most common mutation for achondroplasia, which is only 11 amino acids away from the *FGFR3* mutation for Crouzonodermoskeletal syndrome. To call this disorder "Crouzon syndrome with acanthosis" is unwarranted, because only one *FGFR3* mutation is responsible for all cases; this is in contrast with Crouzon syndrome, which involves more than 30 different *FGFR2* mutations.[38]

Rarely, patients with achondroplasia and hypochondroplasia (both of which involve mutations on *FGFR3*) may also have craniosynostosis (there have been three reported cases of hypochondroplasia and two reported cases of achondroplasia). Saethre–Chotzen syndrome has *TWIST* mutations inside or outside of the coding region that result in haploinsufficiency.[48] Craniofrontonasal syndrome is caused by heterozygous loss-of-function mutations in *EFNB1*. *EFNA4* mutations rarely cause non-syndromal coronal synostosis. Carpenter syndrome, which is an autosomal recessive disorder, is caused by *RAB23* mutations. Boston-type craniosynostosis, which is an autosomal dominant disorder caused by *MSX2* mutations, presents with variable expressivity (coronal synostosis, frontal depression, or cloverleaf skull). Antley–Bixler syndrome is caused by *POR* mutations, and infantile hypophosphatasia is caused by *ALPL* mutation.[44,184]

Complex Craniosynostosis

Background

Complex craniosynostosis, which involves the fusion of multiple cranial sutures, occurs in about 5% of non-syndromic cases.[47] Two thirds of cases involve two affected sutures, whereas one third of cases involve more than two affected sutures.[203] As the number of affected sutures increases, so does the risk of intracranial hypertension and associated mental deficiency. As demonstrated by Renier and colleagues, the incidence of intracranial hypertension rises from 14% to 47% when going from single to several affected sutures.[228,226,227,229,230] In addition, increasing sutural involvement can be accompanied by worsened phenotypic severity. In a series reported by Chumas and colleagues,[34] 59% of cases of sagittal and bilateral lambdoid synostosis had an acute angulation of the posterior skull, which is known in French as *coup de serpe* and means "cut with a scythe." In a similar fashion, marked anterior dysmorphism with frontal bone hypoplasia was found in 23% of cases of metopic and bilateral coronal synostosis.

*References 5, 42, 45, 81, 82, 95, 115, 116, 131, 143, 159, 160, 165-168, 177, 183, 223, 233, 236, 248, 250, 251

Cloverleaf skulls, which represent the extremes of phenotypic severity, are pathogenetically variable (Fig. 30-1).[30,204] Synostosis may involve the coronal, lambdoid, and metopic sutures, which are marked by bulging of the cerebrum through an open sagittal suture or, in some cases, through patent squamosal sutures. Synostosis of the sagittal and squamosal sutures with cerebral eventration through a widely patent anterior fontanel may also be observed. A trilobular skull shape may also occur, with complete synostosis of all cranial sutures in some cases or with widely patent sutures and no craniosynostosis at birth in other instances.[36,51] In addition to being pathogenetically variable, cloverleaf skulls are also etiologically heterogeneous. This condition most commonly occurs with type 2 thanatophoric dysplasia (i.e., in about 40% of cases) with a specific *FGFR3* mutation, but stillborn status or an early demise during very early infancy precludes treatment. Isolated cloverleaf skull occurs in about 20% of cases. It also occurs in about 15% of cases of type 3 Pfeiffer syndrome, and, although the prognosis is guarded, these patients can be treated aggressively.[45,48]

Plagiocephaly is defined as the asymmetric distortion of the skull. Well-known types include synostotic anterior plagiocephaly (unilateral coronal synostosis), synostotic posterior plagiocephaly (unilateral lambdoid synostosis), deformational anterior plagiocephaly, and deformational posterior plagiocephaly.[146,148,268] Among these types, deformational posterior plagiocephaly is common, whereas unilateral lambdoid synostosis is rare. Deformational posterior plagiocephaly can be caused by intrauterine factors such as hypotonia, fetal positioning, and prematurity. This can produce asymmetric flattening of the occiput that becomes favored by infants sleeping on their backs, thereby exaggerating the plagiocephaly. Deformational posterior plagiocephaly has also increased dramatically since the 1992 "Back to Sleep" campaign by the American Academy of Pediatrics, which calls for supine infant sleeping to reduce the risk of sudden infant death syndrome.[44] Finally, rare forms of plagiocephaly can be produced by unilateral frontosphenoidal synostosis and unilateral frontozygomatic synostosis.[44]

Apert Syndrome

Apert syndrome is characterized by craniosynostosis, midface deficiency, symmetric syndactyly of the hands and feet, and other abnormalities* (Figs. 30-2 through 30-5). Most cases are associated with brachycephaly secondary to bicoronal synostosis. Megalencephaly and increased cranial height are characteristic of Apert syndrome; affected children typically display head circumference, length, and weight that are above the normal 50th percentile. Benign distortion ventriculomegaly is also a feature of Apert syndrome, and patent sutures and synchondroses (except for coronal synostosis) are present as well. The frequency of progressive hydrocephalus is much lower than in it is with Crouzon and Pfeiffer syndromes. Central nervous system anomalies may include hypoplasia of the corpus callosum, agenesis of the corpus callosum, agenesis of the septum pellucidum, cavum septum pellucidum, dorsally displaced hippocampi and hippocampal gyri, hypoplastic white matter, and heterotopic gray matter.[46,48]

Skeletal abnormalities with Apert syndrome include symmetric syndactyly of the hands and feet; abnormal shoulders with significant limitation of motion; and abnormalities of the elbows, hips, knees, rib cage, and spine.[46] It should be carefully noted that the radiologic interpretation of the hands, feet, and cervical spine as being affected by so-called "progressive fusion" is very misleading. In actuality, there is a failure of cartilage segmentation during embryonic and fetal life, so these abnormalities are preset (ab initio). These failures in cartilage segmentation cannot be readily observed radiographically at birth. When they do become evident radiographically after birth, they are said to be a "progressive abnormality," which they are not. The same can be said for the cervical vertebrae,[46] as 68% of these patients have cervical abnormalities, particularly involving C5 and C6. Before considering a surgical procedure, magnetic resonance imaging of the brain, radiography of the cervical spine, and the assessment of cardiovascular (10% of patients) and genitourinary (9.6% of patients) anomalies should be carried out.[44,46,48]

Patients with Apert syndrome also suffer from reduced nasopharyngeal dimensions and reduced patency of the posterior choanae; these features pose the risks of respiratory embarrassment, obstructive sleep apnea (OSA), cor pulmonale, and even sudden death. During infancy, patients may be trialed on a nasopharyngeal airway, but tracheostomy may be the only definitive treatment. Clinicians must always maintain a high index of suspicion for OSA and monitor patients for snoring or an unusual amount of daytime somnolence. When either of these is apparent, patients should be referred to a sleep center for proper diagnosis and treatment. It should be carefully noted that, although patients with Apert syndrome very commonly have OSA, the excessive sweating that occurs with this syndrome is not a sign of OSA but rather a consequence of the increased number of sweat and sebaceous glands that accompany the syndrome. Even those patients who have surgical advancement of the midface in combination with continuous positive airway pressure (CPAP) will still have excessive sweating of the head at night and of the hands all the time. Another consequence of an increased number of sweat and sebaceous glands is a high frequency of conglobate acne during adolescence, often with extension to the forearm, the thighs, and the buttocks. The acne vulgaris of Apert syndrome suggests exquisite end-organ responsiveness to steroid hormones.[46]

• **Figure 30-1** A child with a severe form of cloverleaf skull anomaly. At 10 months of age, she was referred to this surgeon and underwent first-stage cranial vault and upper orbital decompression with reshaping. She then required a ventriculoperitoneal shunt for the management of hydrocephalus. When the patient was 3½ years old, posterior cranial vault decompression with reshaping to increase the intracranial volume was performed. When she was 4½ years old, facial bipartition osteotomies in combination with anterior cranial vault reshaping and advancement were carried out. After the cranial vault and facial bipartition procedures, the patient's airway improved, and it was possible to remove the tracheostomy tube. The cranial vault reshaping expanded the intracranial volume, thereby providing more space for the brain. The midface advancement improved the eye proptosis as well as the patient's ability to chew and articulate speech. As part of the staged reconstruction, she will require orthognathic surgery in combination with orthodontic treatment at the time of early skeletal maturity. **A,** Frontal facial and computed tomography (CT) scan views at 10 months of age. **B,** Intraoperative views at 10 months of age after craniotomy and the removal of the cranial vault and the upper orbits. The "bandeau" is in place (3 cm advancement) before the reconstruction of the overlying cranial vault. **C,** Profile views at 2½ and then at 3½ years of age with flattened posterior cranial vault and severe midface deficiency.

Ocular findings include hypertelorism, proptosis (often asymmetric), and down-slanting palpebral fissures. The presence of V-pattern strabismus, which is marked by divergent upgaze and esotropic downgaze, is common and secondary to structural abnormalities of the extraocular muscles (i.e., the absence of the superior rectus muscle). Hyperopia, myopia, and astigmatism can also be present. Strabismus and significant refractive errors can sometimes cause amblyopia. Proptosis in Apert syndrome may require tarsorrhaphies to prevent exposure keratitis.[131]

Hearing loss occurs in 90% of these patients, with 80% of cases resulting from conductive pathology. Inner-ear anomalies are found in all patients; these most commonly present as dilated vestibules, malformed semicircular canals, and cochlear dysplasia.[285] Otitis media is common, and it is possibly related to the presence of cleft palate and accompanying eustachian tube dysfunction.

Oral and maxillofacial anomalies can also be present. The palate can be highly arched and constricted with a median furrow in up to 94% of patients. The hard palate is often shorter than normal, whereas the soft palate is longer and thicker than normal. Clefting of the soft palate occurs in 41% of patients, and a bifid uvula is present in 35%. Dental anomalies include severely delayed eruption (68%), ectopic eruption (50%), and shovel-shaped incisors (30%). Dental crowding is more severe in the maxilla than in the mandible. Common dental deformities include anterior open bite (73%), posterior crossbite (63%), and mandibular overjet (81%).[46,48]

Crouzon Syndrome

Crouzon syndrome is characterized by craniosynostosis, maxillary hypoplasia, shallow orbits, and ocular proptosis.* (Figs. 30-6 through 30-11). Most cases are associated with brachycephaly secondary to bicoronal synostosis; however, trigonocephaly, scaphocephaly, and cloverleaf skull have also been noted. Cranial malformation depends on the order and rate of progression of the sutural synostosis. The cranial volume of patients with Crouzon syndrome is much smaller than that found in patients with Apert syndrome. Central nervous system findings include shunted hydrocephalus (25%), chronic tonsillar herniation (72%), jugular foramen stenosis with venous obstruction (30%), seizures (10.5%), frequent headaches (29%), and mental deficiency (3%).[46,48] As a result of severe maxillary deficiency, patients should be monitored for snoring and excess daytime somnolence. If this is severe during infancy, tracheostomy may be the only option. Older children should be initially worked up with a polysomnographic study. Treatment options range from CPAP therapy to midface advancement on the basis of the severity level.[46]

Cervical vertebral anomalies are found in 25% of patients with Crouzon syndrome, and all involve C2 and C3. Anomalies should be assessed before the patient undergoes anesthesia for any craniofacial procedure. Patients with Crouzon syndrome already have problematic airways as a result of their relatively inflexible necks; thus, cervical anomalies will compound the issue.[46]

Ophthalmologic abnormalities include hypertelorism, pronounced ocular proptosis, exotropia, exposure keratitis, poor vision, and optic atrophy. Luxation of the eye globes may be observed in some instances. Although emergency reduction followed by tarsorrhaphies may be necessary, some patients can luxate and reduce all by themselves.[131]

Mild to moderate conductive hearing deficit occurs in 55% of patients, and atresia of the external auditory meatus is found in 13%. Otitis media is common, and middle-ear disease may be related to the presence of cleft palate and associated eustachian tube dysfunction

Oral findings include lateral palatal swellings (50%), obligatory mouth breathing (32%), bifid uvula (9%), and cleft palate (9%). The maxillary dental arch is shortened and associated with a posterior crossbite, dental crowding, and ectopic eruption of the maxillary first molars. Anterior open bite, mandibular overjet, and crowding of the mandibular anterior teeth are also common.[46]

Pfeiffer Syndrome

Pfeiffer syndrome is characterized by craniosynostosis; midface deficiency; broad thumbs, great toes, or both; brachydactyly; variable soft-tissue syndactyly; and other anomalies (Figs. 30-12 through 30-15).[188,231] Three clinical subtypes have been proposed. Type 1 is representative of the aforementioned description. Type 2 is characterized by cloverleaf skull, elbow ankylosis or synostosis, and a cluster of unusual anomalies in addition to the Type 1 characteristics. Type 3 involves a very short cranial base, severe ocular proptosis, elbow ankylosis or synostosis, and an assortment of unusual anomalies. Types 2 and 3 also include an increased risk for neurodevelopmental difficulties. A favorable outcome can be achieved in some cases with aggressive medical and surgical management; however, normal outcome is not the rule, and neurodevelopmental outcome and life expectancy prognoses remain guarded in most cases.[44] Although these subtypes are useful, they have limited nosologic status, and some clinical overlap does occur.

Craniofacial features include brachycephaly as a result of bicoronal synostosis, hypertelorism, ocular proptosis, and midface deficiency.[44] Distortion ventriculomegaly, progressive hydrocephalus, and cerebellar herniation are common. Progressive hydrocephalus is much more common among patients with Pfeiffer and Crouzon syndromes than it is among those with Apert syndrome. Gyral abnormalities have been observed in some cases.[44] Vertebral anomalies occur in 70% of patients, particularly at C2 and C3, but such anomalies may involve other cervical vertebrae as well as the lumbar vertebrae in some cases. [46] As in Apert and Crouzon syndrome, OSA can affect patients with Pfeiffer syndrome. For a further understanding of diagnosis and therapy, please refer to the relevant discussions in the sections of this chapter about the Apert and Crouzon syndromes. Other anomalies have been noted in some cases, including cardiovascular defects, gastrointestinal issues, and genitourinary anomalies.[44]

Saethre–Chotzen Syndrome

Saethre–Chotzen syndrome is characterized by a heterogeneous phenotypic presentation that involves craniosynostosis, a low-set frontal hairline, facial asymmetry, ptosis of the eyelids, a deviated nasal septum, brachydactyly, partial soft-tissue syndactyly of the second and third fingers, and various skeletal anomalies.[4,33,40,234] Craniosynostosis is facultative and not obligatory (i.e., some patients do not have it). When it is present, the time of onset and the degree of craniosynostosis can be quite variable. Brachycephaly is found most commonly, and this is followed by synostotic anterior plagiocephaly. Frontal bossing, parietal bossing, and occipital flattening can also accompany the cranial deformity. Large late-closing fontanelles and large parietal foramina have also been reported. Ptosis of the eyelids, hypertelorism, and strabismus are common. The ears may be low set, small, and posteriorly angulated, and mild conductive hearing loss is common. Oral anomalies include a narrow or highly arched palate, a cleft palate on occasion, malocclusion, and supernumerary teeth.[40]

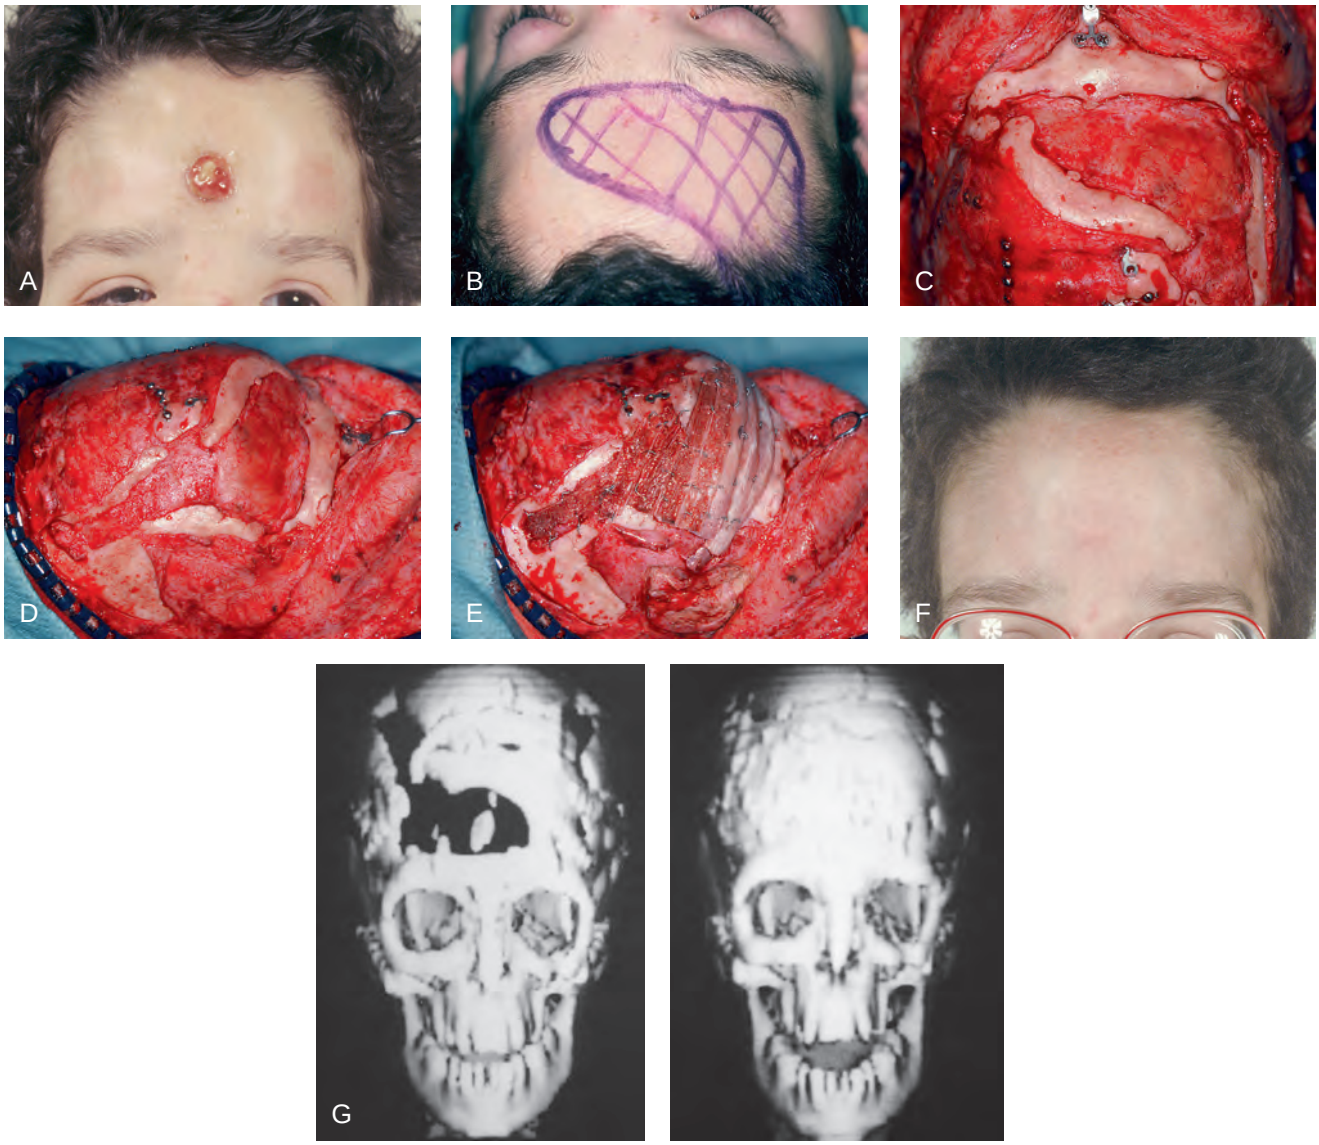
Carpenter Syndrome

Carpenter syndrome is characterized by craniosynostosis (commonly, but not always); preaxial polydactyly of the feet; brachydactyly, clinodactyly, or both; congenital heart defects (these are seen in 33% of patients), such as ventricular septal defect, atrial septal defect, patent ductus arteriosus, pulmonary stenosis, and tetralogy of Fallot; short stature, with a height that is usually below the 25th centile; obesity; and mental deficiency in some cases.[28,39] Craniosynostosis involves the sagittal and lambdoid sutures first, with the coronal suture being the last to close. The head is usually broad, but it is variable in shape, and asymmetry may be a feature. Other features include dystopia canthorum, down-slanting palpebral fissures, epicanthal folds, low-set ears, and a short neck. The mandible may be hypoplastic, and the palate may be narrow or highly arched.[39]

Neurologic Aspects of Craniosynostosis

Generally, craniosynostosis tends to restrict intracranial volume. The earlier synostosis occurs, the more dramatic the effect on subsequent cranial growth and development. The later synostosis occurs, the less the effect on cranial growth and development. Growth restriction also worsens with increasing sutural involvement; complex craniosynostosis with two or more affected sutures demonstrates higher growth restriction as compared with single sutural involvement. There are two exceptions to this observation: scaphocephaly and Apert syndrome. With scaphocephaly,



• **Figure 30-15** A 12-year-old boy with Noonan syndrome. When he was 5 years old, he underwent bilateral total orbital osteotomies with medial translocation for the correction of orbital hypertelorism; this was carried out by another surgeon. When he was 12 years old, he presented to this surgeon with a retruded irregular forehead, shallow orbits, residual proptosis, and midface deficiency. He underwent anterior cranial vault and monobloc osteotomies with horizontal advancement. An occult cerebral spinal fluid leak with drainage through the nose occurred. Eventually, there was erosion through the mid-forehead skin and resorption of a segment of the anterior and lateral cranial vault. One year after the monobloc procedure, the patient was taken back to the operating room for the repair and closure of the cerebral spinal fluid fistula and a cranioplasty that consisted of autogenous split-rib grafts. The cranial vault reconstruction was successful, without further infection or long-term sequelae. **A,** Frontal view of the upper face 6 months after the initial surgery, with a cerebral spinal fluid fistula through central forehead. **B** and **C,** Intraoperative views of the anterior cranial vault documenting the region of bone loss. **D,** Intraoperative lateral view that shows the area of bone loss. **E,** Intraoperative lateral view after autogenous split-rib graft reconstruction. **F,** Frontal view of the upper face 1 year after dura repair and the split-rib reconstruction of the skull defects. **G,** Computed tomography scan views before and after successful split-rib graft cranioplasty.

mechanical forces produce a large head circumference; with Apert syndrome, brain weights have been shown to be above the 97th centile, regardless of age.[46,48]

Mental deficiency is correlated with the number of fused sutures, and it occurs more frequently with two or more sutural involvements than with single-suture synostosis. In addition, mental deficiency occurs more commonly with coronal synostosis than with other single-suture craniosynostoses. With single-suture craniosynostoses (other than coronal), mental deficiency may be more attributed to a brain malformation rather than to growth restriction. This may occur in patients with trigonocephaly and even in some cases of sagittal synostosis.[25]

In the section about Apert syndrome, a distinction was made between benign megalencephaly or distortion megalencephaly and progressive hydrocephalus. The mechanism of hydrocephalus may vary. Although communicating hydrocephalus with obstruction at the level of the basal cisterns is most common, aqueductal stenosis is fairly frequent. Chronic tonsillar herniation occurs in 73% of

patients with Crouzon syndrome as compared with only 1.9% of patients with Apert syndrome.[62] Premature synostosis of the lambdoid suture may be responsible for this finding. It has also been suggested that the obstruction of the venous drainage of the brain may play a role by narrowing the jugular foramina. Some patients are able to compensate well for their hydrocephalus.[25]

Clinicians must maintain a high index of suspicion for hydrocephalus in all patients with craniosynostosis, particularly those with complex or syndromic types.[77,91,108,170,174] Among the syndromic craniosynostoses, shunted hydrocephalus is found in 26.6% of patients with Crouzon syndrome and in 27.8% of patients with Pfeiffer syndrome but in only 6.5% to 8% of patients with Apert syndrome.[46] Increased intracranial pressure in craniosynostosis may be the result of a mismatch in cranial volume to brain growth or of hydrocephalus. Increased intracranial pressure is found most commonly in patients with multiple suture synostoses.[9,26,49,58,122,191,222,226,227-230,245,266] However, recent studies have indicated that increased pressure may also occur in patients with single-suture synostosis. In one report, 3 out of 18 children with scaphocephaly had increased intracranial pressure during 12- to 24-hour recordings.[265]

When pressure is low grade, clinical symptoms can be subtle or absent. Headache is the classic symptom that is associated with increased intracranial pressure of any cause. However, children seem to experience this inconsistently, and infants are not developed enough to communicate their symptoms. The most common physical finding is papilledema, although this may not be as apparent during infancy or early childhood, when bulging may occur at the anterior fontanel instead. Longstanding papilledema may result in optic atrophy and eventual blindness.[25]

Regardless of the cause, increased intracranial pressure tends to rise during rapid eye movement sleep, presumably as a result of increased cerebral blood flow. Indeed, plateaus of increased intracranial pressure that last approximately 10 to 120 minutes have been observed during sleep. Conversely, intracranial pressure may be normal while the patient is awake or between periods of rapid eye movement sleep. Thus, the diagnosis of increased intracranial pressure may be missed by a single lumbar puncture measurement. Reasonably safe ways of long-term, direct measurement of increased intracranial pressure are possible with the use of an epidural pressure transducer to record pressure for at least 12 hours. In this way, the significance of increased intracranial pressure as a contributing factor to mental deficiency can be examined.[25]

With these considerations in mind, the neurologic assessment of patients with craniosynostosis can be performed as follows. The medical history should concentrate on genetic factors as well as the on child's development. The physical examination should include a careful search for associated anomalies, with scrupulous attention paid to each of the cranial nerves (and particularly to cranial nerves II and VIII). Head circumference should be plotted on the standard growth curve. Investigations should include a skull radiograph, head computed tomography (CT) scan, brain magnetic resonance imaging, initial assessment for hydrocephalus, and formal assessment for hearing. An ophthalmologic examination is mandatory. Depending on the findings, a 12- to 24-hour pressure recording should be considered. Whenever possible, a formal developmental or newborn psychologic battery should be administered before surgery. The family should be assessed for psychosocial problems, especially when a complicated course of surgical interventions is contemplated. Follow up by a pediatrician or pediatric neurologist at regular intervals is essential. Assessments at monthly intervals for the first 12 months, every 3 months during the second year, and every 6 months until 6 years of age seem appropriate.[25]

Effects of Midface Deficiency on the Upper Airway

All newborn infants are obligate nasal breathers. Most infants who are born with syndromic craniosynostosis have moderate to severe hypoplasia of the midface. They have diminished nasal, nasopharyngeal, and retropalatal airspaces with resulting increased upper airway obstruction. The affected child is thus forced to breath solely through the mouth. For a newborn infant to ingest food through the mouth, he or she must suck from a nipple to achieve negative pressure and have an intact swallowing mechanism. The neonate with severe midface hypoplasia is unable to accomplish this task while breathing adequately through the nose at the same time. Complicating this clinical picture may be an abnormal palate, enlarged tonsils, and enlarged adenoids. Thus, the compromised infant expends significant energy on respiration, possibly pushing the child into a catabolic state (i.e., a negative nitrogen balance). Failure to thrive can occur in the absence of nutritional support (e.g., nasogastric tube, feeding gastrostomy). It is also essential to establish a secure airway, typically via a tracheostomy, which may require air tubing at night. It is also essential to obtain evaluations from a pediatrician, a pulmonologist, a pediatric otolaryngologist, and a feeding specialist with craniofacial experience to help distinguish minor feeding difficulties from those that require more aggressive treatment.

Sleep apnea may be central, obstructive, or of mixed origin; proper workup and assessment are crucial to the establishment of the correct diagnosis and treatment.* Central apnea may result from intracranial hypertension. If so, the condition should improve upon brain decompression by appropriate cranio–orbital or posterior cranial vault expansion or when effective shunting of the hydrocephalus is accomplished.

OSA has already been addressed in the sections about the Apert, Crouzon, and Pfeiffer syndromes.[105,138,149,190]

*References 2, 35, 79, 92, 101, 105, 106, 114, 135, 141, 162, 172, 173, 175, 181, 185, 187, 190, 275, 284

OSA in a child who is affected by one of these conditions is frequently treated with tracheostomy. It may also be treated by adenoidectomy, tonsillectomy, midface advancement, or CPAP. If left untreated or ineffectively treated, OSA will result in disabilities that include failure to thrive, recurrent upper respiratory infection, cognitive dysfunction, developmental delay, cor pulmonale, and sudden death.[173] Midface hypoplasia in the setting of a craniosynostosis syndrome is often a primary cause of OSA. If feasible, surgical midface advancement is the preferred biologic treatment approach; even with such treatment, some patients will still require a tracheostomy or CPAP therapy.

Clinical signs of OSA may include loud snoring; observed apnea during sleep; excessive perspiration during sleep (except in patients with Apert syndrome, as described previously in this chapter); difficulty during daytime breathing; and daytime somnolence. Polysomnography is essential for accurately diagnosing the type of obstruction (i.e., central, obstructive, or mixed). In the pediatric age group, apnea is defined as the absence of airflow for more than two breaths, whereas hypopnea is defined as a reduction of at least 50% of nasal flow signal amplitude. The apnea–hypopnea index (AHI) is the number of obstructive apneas in combination with hypopneas (followed by desaturations) per hour. The oxygen–desaturation index is the number of desaturations (i.e., ≥4% decrease with respect to the baseline) per hour. A score of less than 1.0 in a child is considered normal. The severity of the condition in children is defined as follows: between 1 and 5 events per hour is considered mild OSA; 6 to 25 events per hour constitute moderate OSA; and more than 25 events per hour results in severe OSA. In the child with a craniosynostosis syndrome and a midface deficiency with documented OSA, neither tonsillectomy nor adenoidectomy generally provides sufficient opening of the upper airway.

Al-Saleh and colleagues completed a retrospective review of children with syndromal craniosynostosis who were referred to the Hospital for Sick Children in Toronto, Canada, between 1996 and 2008 for initial polysomnography to rule out sleep-related disordered breathing.[2] The research confirmed a high prevalence of this type of breathing in children with Crouzon, Apert, Pfeiffer, and Saethre–Chotzen syndromes (N = 35). Despite a spectrum of surgical and non-surgical interventions having been carried out, the complete resolution of the sleep-related disordered breathing could not be routinely achieved.

Ishii and colleagues used lateral cephalometric radiographs to evaluate the nasopharyngeal airway after Le Fort III advancement in patients with Apert or Crouzon syndrome and OSA.[114] The researchers documented improvement in the nasopharyngeal airway space after successful midface advancement surgery. Arnaud and colleagues reviewed respiratory improvement in patients with syndromic craniosynostosis and OSA after monobloc (MB) advancement.[8] Eighty-eight percent of patients (n = 16) showed improvement as measured by oxygen level during sleep; 4 of 6 patients underwent successful tracheostomy decannulation. In one patient, a tracheostomy was required 6 months after midface advancement for severe and recurrent OSA.

Twenty-four months after MB advancement, Witherow and colleagues documented the significant improvement of airway obstruction on polysomnography in all patients who had been diagnosed with Apert, Crouzon, or Pfeiffer syndrome.[280] Before MB advancement, 14 patients were managed with tracheostomy or CPAP therapy for severe OSA. Of these 14 patients who were undergoing MB advancement for severe OSA, only 43% (n = 6) had resolution of their OSA; 8 of 14 patients (57%) remained dependent on tracheostomy or CPAP despite MB advancement.

Nelson and colleagues studied 18 patients with craniosynostosis syndromes who also had coronal synostosis and midface deficiency.[172] Eighty-three percent (16 of 18 patients) were treated with tracheostomy or CPAP for known OSA before midface advancement. After the midface advancement procedures, five of the tracheostomy patients were decannulated; in six others, CPAP was no longer required. This represents a 73% (11 of 15 patients) initial success rate for the relief of OSA. The mean postsurgical follow up was 3 years.

In patients with syndromic craniosynostosis who were undergoing midface advancement, the lack of universal success for the relief of OSA could result from a combination of factors, including inadequate midface advancement; midface relapse after initial advancement; other anatomic sites or conditions of airway obstruction not addressed by midface advancement (e.g., septum, turbinates, soft palate, tonsils, adenoids, or mandible; tracheomalacia); a central sleep apnea component; or inadequate contraction of the pharyngeal dilator muscles during sleep. The anatomy of the upper airway is different for each syndrome and also widely variable within each syndrome. Patients with a craniosynostosis syndrome and OSA who are non-responders to an effective midface advancement may have pharyngeal wall collapse caused by compromised pharyngeal dilator muscle function during sleep. Although a tendency for airway collapse can be overcome by midface advancement, the patient must also have the sufficient ability to control, contract, and maintain the tone of the pharyngeal muscles while asleep.

Morphologic Considerations

Examination of the patient's entire craniofacial region should be meticulous and systematic. The skeleton and the soft tissues are assessed in a standard way to identify all normal and abnormal anatomy.[65,66,68,202,205,206,211,212,216,217,272,273] Specific findings tend to occur in particular malformations, but each patient is unique. The achievement of symmetry, normal proportions, and the reconstruction of specific aesthetic units is essential to forming an unobtrusive face in a child who is born with one of the craniosynostosis syndromes.

Fronto–Forehead Aesthetic Unit

The fronto–forehead region is dysmorphic in an infant with a craniosynostosis syndrome. Establishing the normal position of the forehead is critical for overall facial symmetry and balance. The forehead may be considered as two separate aesthetic components: the supraorbital ridge/lateral orbital rim region and the superior forehead. The supraorbital ridge/lateral orbital rim unit includes the nasofrontal process and the supraorbital rim extending inferiorly down each frontozygomatic suture toward the infraorbital rim and posteriorly along each temporoparietal region. The shape and position of the supraorbital ridge/lateral orbital rim region is a key element of upper facial aesthetics. In a normal forehead, at the level of the nasofrontal suture, an angle that ranges from 90 to 110 degrees is formed by the supraorbital ridge and the nasal bones when the face is viewed in profile. In addition, the eyebrows, which overlie the supraorbital ridge, should be anterior to the cornea. When the supraorbital ridge is viewed from above, the rim should arc posteriorly to achieve a gentle 90-degree angle at the temporal fossa with a center point of the arc at the level of each frontozygomatic suture. The superior forehead component, which is about 1.0 to 1.5 cm up the supraorbital rim, should have a gentle posterior curve of about 60 degrees, thus leveling out at the coronal suture region when the face is viewed in profile.

Posterior Cranial Vault Aesthetic Unit

The symmetry, form, and adequate intracranial volume of the posterior cranial vault are closely linked. Posterior cranial vault flattening may result from unilateral or bilateral lambdoid synostosis, which is rare; previous craniectomy with reossification in a dysmorphic flat shape, which is frequent; or postural molding as a result of intrauterine positioning or repetitive supine sleep positioning. A short anteroposterior cephalic length may be misinterpreted as an anterior cranial vault (forehead) problem when the occipitoparietal (posterior) skull represents the primary region of the abnormality. Careful examination of the entire cranial vault is essential to defining the dysmorphic region so that, when indicated, appropriate cranial vault expansion and reshaping may be carried out.

Orbito–Naso–Zygomatic Aesthetic Unit

In the craniosynostosis syndromes, the orbito–naso–zygomatic regional abnormality is a reflection of the cranial base malformation. In patients with Crouzon syndrome, when bilateral coronal suture synostosis is combined with skull base and midface deficiency, the orbito–naso–zygomatic region will be dysmorphic and consistent with a short anteroposterior and wide transverse anterior cranial base. In patients with Apert syndrome, the nasal bones, orbits, and zygomas—like the anterior cranial base—are transversely wide as a result of the anterolateral bulging of the temporal lobes of the brain and horizontally short (i.e., retruded); this results in a shallow, hyperteloric, "reverse curved" upper midface. Surgically advancing the midface without simultaneously addressing the increased transverse width and the "reverse curve" will not adequately correct the dysmorphology.

Maxillary/Nasal Base Aesthetic Unit

In the patient with a craniosynostosis syndrome and a midface deficiency, the upper anterior face is vertically short (i.e., from the nasion to the maxillary incisor), and there is a lack of horizontal anteroposterior projection. These findings may be confirmed through cephalometric analysis, which indicates the presence of a sella–nasion–A point angle that is less than the mean value as well as a short upper anterior facial height (i.e., from the nasion to the anterior nasal spine). The width of the maxilla in the dentoalveolar region is generally constricted, with a highly arched palate. To normalize the maxillary/nasal base region, multidirectional surgical expansion and reshaping are generally required. The abnormal maxillary lip-to-tooth relationship and the occlusion are improved through Le Fort I segmental osteotomies and orthodontic treatment as part of the staged reconstruction. The mandible and the chin are frequently secondarily involved and will benefit from surgical repositioning as part of the orthognathic correction.

Surgical Approach to Craniosynostosis Syndromes

Historical Perspectives

As early as 1890, Lannelogue[134] and then Lane[133] described a surgical approach to the treatment of craniosynostosis. Lannelogue's aim was to remove the fused suture (i.e., strip craniectomy) in the hope of controlling the problem of brain compression within a congenitally small cranial vault. By the turn of the century, Harvey Cushing, who was the most prominent neurosurgeon of his day, suggested that surgical intervention for the problem of craniosynostosis was misdirected and that more attention should instead be given to the schooling of these children.[55] Shillito disagreed with Cushing and enthusiastically supported the concept of surgical intervention to improve the outlook for these children.[243] He believed that the linear "strip" craniectomy of the fused sutures would "release" the skull and allow the cranium to reshape itself and continue to grow in a normal and symmetric fashion. The strip craniectomy procedures were supposed to allow for a new suture line at the site of the previous synostosis. With the realization that this goal was not biologically feasible, attempts were made to remove portions of the cranial vault surgically and leave large open areas or to use the removed segments as free grafts to refashion the cranial vault shape. Problems with these methods included uncontrolled postoperative skull molding,

reossification into dysmorphic configurations, and the occurrence of large residual skull defects.

The concept of the simultaneous release of the fused suture in combination with more meticulous cranial vault reshaping in infants was initially suggested by Rougerie and colleagues[232] and then refined by Hoffman and Mohr in 1976 for children who were born with unilateral coronal synostosis.[107] In 1977, Whitaker and colleagues proposed a more formal anterior cranial vault and orbital reshaping procedure for unilateral coronal synostosis.[279] Marchac and Renier published their experience with a "floating forehead" technique to manage craniosynostosis during infancy; this consisted of simultaneous unilateral coronal and bilateral coronal suture release and forehead and upper orbital osteotomies with advancement.[144] Unfortunately, the "floating forehead" technique resulted in unpredictable reossification of the open cranial vault areas.[145] In addition, bitemporal constrictions and bulging of the skull concavities were frequent occurrences as reossification occurred. In any case, the hope for midface growth did not materialize.

During the 1950s, Gillies and Harrison reported their experience with an extracranial Le Fort III osteotomy to improve the anterior projection of the midface in an adult with Crouzon syndrome. The initial Gillies procedure was actually carried out in 1942.[89] Gillies mobilized the midface via a variety of osteotomies performed through skin incisions directly over each osteotomy site. The midface was mobilized and advanced, and intermaxillary fixation was applied. After the removal of the intermaxillary fixation (i.e., 2 weeks after the operation) a metal cast-cap dental splint was attached to a plaster headcap and maintained for 3 weeks. There was no evidence that Gillies used bone grafts to bridge the surgical gaps that were created. The early enthusiasm for this technique later turned to discouragement when the patient's facial skeleton relapsed to its preoperative status. Relapse occurred at the maxillary incisor level and also resulted in ocular proptosis.

Dr. Tessier was aware of the previous work of Gillies and its accompanying difficulties. In 1967, Tessier described a new intracranial–cranial base approach to the management of Crouzon syndrome.[242] This work was first presented in France at a meeting in Montpellier in 1966 and then again the following year at the International Plastic Surgery Meeting in Rome.[252-254] Tessier's landmark presentations and publications were the beginning of modern craniofacial surgery (see chapter 2). [252-264] To overcome the earlier problems encountered by Gillies, Tessier developed an innovative basic surgical approach that included new locations for the Le Fort III osteotomy, a combined intracranial–extracranial (cranial base) approach, the use of a coronal skin incision to expose the upper facial bones, and the use of fresh autogenous bone graft. He also applied an external fixation device to help maintain bony stability until healing had occurred.

In 1971, Tessier described a single-stage frontofacial advancement in which the fronto–orbital bandeau was advanced as a separate element in conjunction with the Le Fort III complex below and the frontal bones above.[256] Seven years later, Ortiz-Monasterio and colleagues refined the MB osteotomy to advance the orbits and midface as one unit; this was combined with frontal bone (anterior cranial vault) repositioning to correct the upper and midface deficiency associated with Crouzon syndrome.[178,179] In 1979, Van der Meulen described the medial fasciotomy for the correction of midline facial clefting.[267] Van der Meulen split the MB osteotomy vertically in the midline, removed central nasal and ethmoid bone, and then moved the two halves of the facial skeleton together for the correction of the orbital hypertelorism. To correct the midface dysplasia and the associated orbital hypertelorism in patients with Apert syndrome, Tessier refined the vertical splitting and reshaping of the midline split MB segments, thereby correcting the midface deformity in three dimensions via a procedure that is now known as *facial bipartition.* Wolfe and colleagues,[281,282] Kawamoto,[19] and Posnick and colleagues[198,207,208,220] have all independently documented the advantages of Tessier's facial bipartition technique for the correction of the upper and midface abnormalities associated with Apert syndrome. The widespread use of autogenous cranial bone grafting has virtually eliminated the need for rib and hip grafts when bone replacement is required during cranio–orbito–zygomatic procedures.[213] This represents another of Tessier's contributions to craniofacial surgery.[255]

In 1968, Luhr introduced the use of small metal (vitalium) plates and screws to stabilize maxillofacial fractures and then osteotomies (see Chapter 2). In current practice, the use of internal miniplate and microplate and screw (titanium) fixation of various sizes is the preferred form of rigid fixation when the stability and three-dimensional craniomaxillofacial reconstruction of multiple osteotomized bone segments and grafts are required. In infants and young children, resorbable materials are now generally used for the stabilization of non–load-bearing osteotomy segments (e.g., the cranial vault).[139,196,199,221] This avoids the issues or uncertainty regarding growth restriction and brain trauma from retained non-resorbable hardware.

Philosophy Regarding the Timing of Surgery

In considering both the timing and type of intervention, the experienced surgeon will take several biologic realities into account, including the natural course of the malformation (i.e., progressively worsening dysmorphology versus a nonprogressive craniofacial abnormality); the tendency for growth restriction in operated skeletally immature bones (i.e., akin to the maxillary hypoplasia that occurs following cleft palate repair); the relationship between the underlying developing viscera (i.e., brain) and the congenitally affected and/or surgically altered skeleton (i.e., brain compression if the cranial vault is not expanded); and the child's airway needs (i.e., midface deficiency resulting in OSA).

To limit impairment while simultaneously achieving long-term preferred facial aesthetics and head and neck

function, the surgeon must ask an essential question, "*during the course of craniofacial development, does the operated-on facial skeleton of a child with a craniosynostosis syndrome tend to grow abnormally, resulting in further distortions and dysmorphology, or are the initial positive skeletal changes achieved (at operation) maintained during ongoing growth?*" Unfortunately, the proposed theory that craniofacial procedures carried out in early infancy will "unlock growth" has not been documented through the scientific method.[194,200-206,218,219]

Final reconstruction of the upper midface deformities in those born with a craniosynostosis syndrome can be managed as early as 7 to 10 years of age. By this age, the cranial vault and orbits normally attain approximately 85% to 90% of their adult size. Whenever feasible, waiting until the maxillary first molars have erupted is also preferred. When the "upper midface" reconstruction is carried out after this age, the objective is to attain adult morphology in the cranio-orbito-zygomatic region with the expectation of a stable result (no longer influenced by growth) once healing has occurred. Psychosocial considerations also support the age 7 to 10 years time frame for the upper midface procedure. When a successful reconstruction is achieved at this age, the child may progress through school with an opportunity for a healthy body image and self-esteem.*

Management of the Upper Midface Deformity in Children and Young Adults

Incision Placement and Soft-Tissue Management

For the exposure of the craniofacial skeleton above the Le Fort I level, the approach used is the coronal skin incision. This allows for relatively camouflaged access to the anterior and posterior cranial vault, the orbits, the nasal dorsum, the zygomas, the upper maxilla, the pterygoid fossa, and the temporomandibular joints. For added cosmetic advantage, the placement of the coronal incision more posteriorly on the scalp and with postauricular rather than preauricular extensions is useful.[214] When the exposure of the maxilla at the Le Fort I level is required, a circumvestibular maxillary intraoral incision is used. Unless complications occur that warrant unusual exposure, no other incisions are required to manage any aspect of reconstruction in patients with a craniosynostosis syndrome. These incisions (i.e., coronal [scalp] and maxillary [circumvestibular]) may be reopened as needed to further complete the individual's staged reconstruction.

A layered closure of the coronal incision (i.e., the galea and the skin) optimizes healing and limits scar widening. Resuspension of the midface periosteum to the temporalis fascia may facilitate the redraping of the soft tissues. Each lateral canthus should be reattached in a superoposterior direction to the newly repositioned lateral orbital rim. In children, the use of chromic gut on the skin may obviate the need for postoperative suture or staple removal.

Management of the Ventricular System

In the patient with a craniosynostosis syndrome who is to undergo intracranial volume expansion with the concurrent management of hydrocephalus as part of the reconstruction, the potential for morbidity increases.[25,77,91,108,170,174] Complications may arise from either excessive cerebrospinal fluid drainage (overshunting) or inadequate shunting that leads to increased intracranial pressure. With overshunting there is decreased central nervous system mass to fill any surgically created retrofrontal dead space. Uncontrolled hydrocephalus may result in raised intracranial pressure, which leads to its own set of problems. In either situation, fronto–facial advancement via an intracranial approach to the midface or isolated cranial vault expansion procedures should be thoughtfully staged with ventriculoperitoneal shunt management. We believe that the presence or absence of a ventriculoperitoneal shunt is not in itself a major factor in the success of a fronto–facial advancement procedure. An important aspect is the satisfactory physiologic function of the ventricular system, with or without the placement of a shunt. Ultimately, the decision regarding the need for and sequencing of shunting is based on the patient's neurologic findings and the neurosurgeon's judgment. In a patient with a ventriculoperitoneal shunt in place before the surgery, experienced neurosurgical evaluation, including imaging studies of the ventricular system, is carried out to confirm satisfactory physiologic function.

Upper Midface Reconstruction Options

The osteotomy selected (i.e., extra cranial Le Fort III or intracranial, monobloc or facial bipartition) to manage the upper midface dysmorphology in the individual with a craniosynostosis syndrome should reflect the presenting skeletal deformities and provide a realistic opportunity for long term upper midface (naso-orbito-malar) region aesthetic enhancement.

A main objective of this phase of reconstruction is to "normalize" the orbits, zygomas, and cranial vault. Correction of the maxillo-mandibular deformity will require orthognathic surgery including at a minimum a separate Le Fort I osteotomy. The patient specific dysmorphology will depend on the original malformation, the previous procedures carried out, and the effects of ongoing growth.

When evaluating the upper and midface morphology in the mixed dentition child or young adult born with *Crouzon syndrome*, one should note: 1) if the supraorbital ridge is in good position when viewed from the sagittal plane (are the depth of the upper orbits adequate?); 2) if the midface and forehead have an acceptable arc of rotation in the transverse plane (is the midface arc concave?); and 3) if the root of the nose and orbits are of normal width (is there orbital hypertelorism?). If these structures are confirmed to be with acceptable morphology, then there is no need to further reconstruct the forehead and upper orbits. In those few,

*References 8, 10, 11, 23, 32, 36, 56, 57, 63, 69, 70-72, 89, 97, 109, 110, 113, 117, 120, 119, 136, 149-151, 155-158, 169, 171, 176, 180, 189, 192, 195, 197, 215, 235, 239, 241, 244, 277

craniosynostosis syndrome patients, in whom the residual deformity is only in the lower half of the orbits, the zygomatic buttress, and the maxilla an extracranial Le Fort III osteotomy is likely to be effective treatment.

If the supraorbital region, anterior cranial base, zygomas, root of the nose as well as the lower orbits, and maxilla all remain deficient in the sagittal plane (horizontal retrusion), then an MB is indicated. In these patients, the forehead is also generally flat and retruded and will require reshaping and advancement. If upper midface hypertelorism (increased transverse width) with midface flattening (horizontal retrusion) and a concave facial curvature (reverse facial arc) is also present, then the MB unit is split vertically in the midline (facial bipartition). A wedge of interorbital (nasal and ethmoidal) bone is removed, and the orbits and zygomas are repositioned medially while the maxillary arch is widened. A facial bipartition is rarely required in *Crouzon syndrome* but the MB is. When a monobloc or facial bipartition osteotomy is carried out as the "upper midface" procedure, additional segmentation of the upper and lateral orbits may also be required to normalize the morphology of the orbital aesthetic units.

For almost all *Apert syndrome* patients, facial bipartition osteotomies combined with further cranial vault reshaping permits a better correction of the dysmorphology than can be achieved through any other upper midface procedure (i.e., MB or Le Fort III). When using facial bipartition osteotomies, correction of the concave midface arc of rotation is also possible. This further reduces the stigmata of the Apert "flat, wide and retrusive" facial appearance. The facial bipartition allows the orbits and zygomas to shift to the midline (correction of hypertelorism) as units while the maxilla is simultaneously widened (i.e., relief of the V-shaped face). Horizontal advancement of the reassembled upper midface complex is then possible to improve orbital depth and zygomatic length. The forehead is generally flat, tall, and retruded, with a constricting band just above the supraorbital ridge. Reshaping of the anterior cranial vault is also simultaneously carried out. A Le Fort III osteotomy is virtually never adequate for an ideal correction of the residual upper midface anomalies documented in *Apert syndrome*.

The study by McCarthy confirms that the Le Fort III osteotomy is not effective as an aesthetic option to manage the upper midface deformity in the majority of craniosynostosis syndrome patients (see section later in this chapter concerning Le Fort III option).[276] By anatomic design, the Le Fort III prevents management of the whole orbital aesthetic unit during one operative setting. Therefore a major aesthetic shortcoming of the Le Fort III osteotomy, when its indications do not fit the presenting dysmorphology, is the creation of irregular step-offs in the lateral orbital rims. This will occur even when only a moderate Le Fort III advancement is carried out. These lateral orbital step-offs will be visible to the casual observer as unattractive at conversational distance and surgical attempts at modification performed later will be suboptimal. Another problem with the Le Fort III osteotomy is the difficulty in judging an ideal orbital depth. This frequently results in either residual proptosis or enophthalmos. Simultaneous correction of upper face (orbital) hypertelorism and the concave midface arc-of-rotation typical in Apert syndrome is also not possible with the Le Fort III procedure. Excessive lengthening of the nose, accompanied by flattening of the nasofrontal angle, will also occur if the Le Fort III osteotomy is selected when the skeletal dysmorphology favors an MB or facial bipartition. Unfortunately, it is not possible to later correct the elongated nose or the flattened naso-frontal angle. To avoid these short comings, it is not a matter of becoming more proficient at the Le Fort III osteotomy or simply "managing the overlying soft tissues" in a different way (i.e., canthopeties or midface lift). The Le Fort III osteotomy is not consistent with the presenting dysmorphology in most craniosynostosis syndrome patients and, therefore, will not provide the opportunity to achieve the desired aesthetic result. Nevertheless, the Le Fort III is often considererd the "go to" approach by surgeons as it is: 1) an extracranial procedure; 2) requires less surgeon skill/experience; 3) is less likely to result in significant blood loss; and 4) is less likely to result in perioperative complications (i.e., cranionasal fistula, intracranial abscess, bone resorption).

In most syndromal craniosynostosis patients, a suboptimal aesthetic result will occur if the surgeon attempts to simultaneously adjust the orbits and idealize the occlusion using the Le Fort III, MB or facial bipartition osteotomy without completing a separate Le Fort I osteotomy. The degree of horizontal deficiency observed at the orbits and at the maxillary dentition are rarely uniform. If a Le Fort I osteotomy to separate the "lower midface" from the "upper midface" complex is not carried out, excess advancement at the orbits with enophthalmos is likely to occur as the surgeon attempts to achieve a positive overjet at the incisors. The Le Fort I osteotomy is generally *not* performed at the time of the "upper midface" procedure. This will await skeletal maturity and is combined with orthodontic treatment. Until then, a degree of an Angle class III anterior open bite negative overjet malocclusion will remain. When the mature teenage or adult patient presents for surgical correction and requires both "upper midface" (i.e., naso-orbito-zygomatic) and "lower midface" (i.e., maxilla) management the procedures may be carried out simultaneously.

Monobloc and Facial Bipartition Osteotomies (Intracranial Approach to the Orbits and the Midface)

Cranial vault reconstruction in the child with a craniosynostosis syndrome should provide space for the compressed brain to expand. Immediately after completing cranial vault and monobloc (MB) or facial bipartition (FB) osteotomies with advancement, extradural (retrofrontal) dead space remains in the anterior cranial fossa above the skull base gap created by the osteotomy.[208] The skull base gap is in direct communication with the nasal cavity. Therefore, the postoperative recovery may be complicated by cerebrospinal fluid leakage across the skull base gap followed by infection,

fistula formation, and subsequent bone resorption in the glabella region. After fronto–facial advancement by either MB or FB, the communication between the nasal cavity and the cranial fossa must be managed to limit these potential complications. The most effective method to do so remains unclear, but all agree that it is a critical aspect for successful reconstruction. Technical aspects of management include the following: 1) gentle tissue handling; 2) achieving good hemostasis; 3) effective repair of dural tears; 4) avoidance of over expansion of the cranial vault; 5) maximum separation of dura and nasal mucosal tissue planes (i.e., interposing tissue such as bone grafts, tissue sealants, and flaps); 6) rigid plate and screw fixation of the osteotomies and bone segments; 7) avoidance of pressure gradients across the opening to facilitate nasal mucosa healing; and 8) prevention of too much or too little ventriculoperitoneal shunting.

After cranio–orbital reconstruction in the infant with a craniosynostosis syndrome, rapid filling of the expanded intracranial volume by the previously compressed frontal lobes of the brain has been documented.[208] This has also been shown to occur after MB and FB advancement in children and young adults.[249] More gradual filling of the space is thought to occur in older adults. At the time of the MB or FB osteotomies, the nasal cavity can be sealed from the cranial fossa by doing the following: 1) inserting pericranial tissue; 2) placing bone grafts to bridge the osteotomy gaps; and 3) using tissue sealants. This provides time for the re-epithelialization (i.e., healing) of the nasal mucosa. Until the torn nasal mucosa heals, communication between the nasal cavity and the anterior cranial fossa may result in the transfer of air, fluid, and bacteria followed by infection and naso–cranial fistula formation. The postoperative continuation of nasotracheal intubation for several days and nasopharyngeal tube placement after extubation have also proven useful to limit pressure gradients across the communication. The avoidance of positive pressure ventilation, the enforcement of sinus precautions, and the restriction of nose blowing further limits the reflux of air, fluid, and bacteria early after surgery.

Four clinical studies clarify issues of morbidity related to MB or FB osteotomies for the reconstruction of an individual with a craniosynostosis syndrome.

Posnick and colleagues studied the issues of retrofrontal dead space; communication across the skull base osteotomy gap; and associated morbidity in a consecutive series of children in the mixed dentition and young adults in the permanent dentition (n = 23) who were undergoing either MB or FB osteotomies in combination with cranial vault expansion.[208] The procedures were carried out by a single craniofacial surgeon (Posnick) and one of three neurosurgeons at a single tertiary care hospital from 1987 to 1991. The extradural (retrofrontal) dead space was measured from consistent CT scan images at specific postoperative intervals (immediate, 6 to 8 weeks, and 1 year). The study confirmed the presence of an immediate retrofrontal dead space that generally filled in with the expanding brain and dura by 6 to 8 weeks after surgery. Specific intraoperative maneuvers were undertaken by the surgeons to close the nasofrontal communication, including flaps, fibrin glue, bone grafts, and Gelfoam. After surgery, care was taken to limit a pressure gradient across the communication (via the repair of dural tears, sinus precautions, and nasal stenting), with the objective of providing time for nasal mucosa healing. The infection rate in this study group was limited to 2 of 23 patients (9%). In both patients who developed an infection, a retrofrontal (extradural) fluid collection was noted, with drainage across the residual nasofrontal communication into the nose. Both patients healed without significant comorbidity (i.e., brain or eye injury) but did require further reconstruction of the resorbed portions of the anterior cranial vault and the supraorbital ridges (see Fig. 30-15).

Wolfe completed a critical analysis of 81 MB advancements carried out over a 27-year period.[281] This was a retrospective chart analysis of a series of patients who underwent either MB (frontofacial) advancement (MFFA) or FB (MFFA plus FB). The procedures were carried out at seven different craniofacial centers and included 49 MFFA and 32 MFFA plus FB. The MFFA and MFFA plus FB osteotomies were either placed in their preferred location in the operating room (standard approach) or gradually distracted (DO technique) with internal or external devices. Complications included two deaths (cardiac arrest in one patient and complications arising from hypovolemia in the other). One case was aborted as a result of a large-volume blood loss; there were three infections or sequestrations and one persistent cerebrospinal fluid leak (no meningitis). There were significant complications documented in the DO group and fewer in the non-DO group. Blood loss and operative time were equivalent for both standard and DO techniques. Interestingly, the incidence of infection and cerebrospinal fluid leaks was not diminished with the use of the alternative distraction DO approach. The author also concluded that, for the majority of patients, the standard approach offered improved morphologic results. The author then compared the morphologic results of the MMFA and MMFA plus FB with those of the extracranial Le Fort III option and concluded that the Le Fort III was less favorable. Regardless of the technique used, all patients required orthognathic surgery (at the Le Fort I level) to complete the reconstruction.

Bradley and colleagues completed a single-center retrospective study that compared differences in morbidity in a series of patients who were born with a craniosynostosis syndrome and who then underwent MB osteotomy for the correction of upper and midface anomalies or hypoplasia.[19] The authors describe three different sequential treatment groups that were followed during a period of 23 years. Group I patients (1979 to 1989; n = 12) underwent MB osteotomies without any special attention paid to the retrofrontal dead space or the communication through the skull base between the anterior cranial fossa and the nasal cavity. Group II patients (1989 to 1995; n = 11) underwent MB

osteotomies with various attempts at closure of the skull base gap with pericranial flaps and fibrin glue. Group III (1995 to 2002; n = 24) patients underwent MB osteotomies without immediate advancement. An internal distraction device was placed across the osteotomized zygomatic arch on each side. After a 7-day latency period, the advancement of the MB and forehead unit was initiated at 1 mm per day for approximately 2 to 4 weeks. The infection rate for Group III patients was significantly lower (2 of 24 [8%]) than it was for those in Groups I and II. Neither of the two infections in Group III resulted in bone loss. Group I patients had the greatest morbidity likely as a result of the limited fixation performed during the 1970s and 1980s.

As described by Bradley and colleagues, the DO technique does allow more time for the brain to expand into the retrofrontal dead space after the completion of an MB osteotomy (i.e. delayed for 7 days) before advancing the upper midface.[19] In theory, this should facilitate early nasal mucosa healing and thereby limit the communication of fluid, air, and bacteria across the surgically created skull base gap. This likely explains the drop in infection rate in the Group III patients as compared with the Group I and II patients. The rate of infection in Bradley's Group III patients, who were treated with a DO approach, essentially matches that of the patients described by Posnick and colleagues who were treated with a standard approach (8% and 9%, respectively).

Bradley and colleagues also described greater advancement in Group III (DO approach) patients as compared with Group I and II patients.[19] Confounding variables may explain these differences, including increased surgical experience during the later years of the study (i.e., group III patients) and the impact of complications during the earlier years of the study (i.e., extremely high rates of infection in Groups I and II), which likely resulted in relapse and limited the long-term midface advancement. More importantly, there was no correlation between the number of millimeters of MB advancement and either greater functional gains or enhanced facial aesthetics.

COMMENT: With an MB osteotomy, as much aesthetic damage is done by overadvancement (enophthalmos) as by underadvancement (residual eye proptosis). In addition, the achievement of a "normal" occlusion is not usually a treatment objective at the time of MB advancement. Accomplishing an ideal occlusion without creating enophthalmos generally requires a separate Le Fort I osteotomy to differentially reposition the maxilla.

A fourth clinical study sheds further light on this subject. **Ahmad and colleagues** described a series of 12 children who were born with a craniosynostosis syndrome who also had multiple functional problems, including the following: 1) raised intracranial pressure as a result of a diminished cranial vault volume; 2) exposure of the eyes (i.e., corneal irritation) as a result of shallow orbits; 3) airway obstruction from a reduced upper airway space (i.e. OSA); and 4) feeding difficulties.[3] Each of the study patients underwent fronto–facial (MB) advancement with the use of DO techniques. The mean age at operation was 18 months (range, 4 to 30 months). The mean advancement was 16.6 mm at the forehead level and 17 mm at the midface level. Ocular protection and the reduction of intracranial pressure (when raised) was achieved in all children. At least a degree of airway improvement was achieved in all but one child. The authors subjectively state that there was marked improvement in every patient's appearance. Complications included cerebrospinal fluid leaks (2 of 12 patients [16.6%]); pin-site infections (3 of 12 patients [25%]); external DO device frame slippage that required replacement (2 of 12 patients [16.6%]); and overadvancement with resulting enophthalmos (1 of 12 patients [8.4%]). In addition, one patient died 9 months after the procedure in conjunction with tracheal reconstruction. The published article was discussed by **Hopper**,[111] who recommends that clinicians consider a less invasive approach and accept limited aesthetics objectives in an attempt to lower perioperative morbidity. The approach that he suggests includes the following: 1) either anterior cranial or posterior cranial vault expansion without simultaneous midface advancement to relieve intracranial pressure; 2) extracranial Le Fort III advancement without simultaneous cranial vault expansion to open the upper airway; 3) tarsorrhaphies to protect the eyes from exposure rather than orbital expansion; and 4) continued tracheostomy for airway management rather than midface advancement.

COMMENT: The four studies reviewed and the discussion by Hopper that followed demonstrate the wide variation of opinions on how best to reconstruct individuals with a craniosynostosis syndrome. In this author's opinion, for the majority of these children, only the MB or facial bipartition osteotomies offer a realistic opportunity to achieve close to normal morphology and the opportunity to develop healthy self-esteem. Favorable craniofacial function is expected to follow the enhanced facial form. This includes cranial vault expansion (i.e., relief of ICP); orbital expansion (i.e., relieve of proptosis and eye protection); and upper airway expansion (i.e., relief of OSA and improved breathing during the day). Gains in mastication, swallow mechanism, speech articulation, breathing, vision, and cognitive function are also expected.

For the individual with a craniosynostosis syndrome, to achieve the most favorable facial harmony and head and neck function, the surgeon needs both an aesthetic sense and the technical expertise to execute effective upper/midface surgical procedures. Several key aspects include:

1. The ability to remove, segment, reshape and then stabilize the cranial vault
2. The ability to separate the orbits and midface as a unit MB from the skull base
3. The ability to segment and reshape the upper orbits of the MB including interposing bone grafts as needed to reconstruct each orbital aesthetic unit during a single operative setting.
4. The ability to separate the MB into halves (facial bipartition) and then three-dimensionally reposition and stabilize (plate and screw fixation) the two facial halves to achieve the most favorable morphology in all three planes (i.e., pitch, role, yaw orientation). This often requires increasing the maxillary width (i.e., arch expansion) and decreasing the upper face width (i.e., correction of hypertelorism of the orbits, zygomas, and bitemporal regions). Facial bipartition also provides the ability to correct the transverse facial arc of rotation. An example is changing the concave facial arc of rotation (i.e., yaw orientation) in Apert syndrome.

In current clinical practice when either a monobloc or facial bipartition osteotomy is selected, the technique of "distraction" to gradually advance the upper/midface, after closure of the wounds is frequently used. Any potential for reduced infection across the skull base using the DO technique should be considered in light of limitations to achieving the aforementioned aesthetic objectives (points 1 to 4 mentioned previously). At the same time, clinicians must take into account the procedure specific morbidity associated with the DO technique including: 1) pin tract infection; 2) soft tissue scarring; 3) hardware loosening requiring re-application; 4) brain trauma from the screw penetration; and 5) the need for device removal. 6) In addition, effective DO technique depends on the patient's, the patient's family, and the clinician's continued commitment to staying the course after surgery (approximately 4 months). *It is hoped that in the future, clinicians will both master the known surgical techniques and also find novel solutions to manage the potential for morbidity associated with MB and facial bipartition osteotomies (i.e., CSF leak, intracranial abscess, and bone resorption) while focusing to the aesthetic details so that individuals with a craniosynostosis syndrome can more commonly benefit from the procedures inherent advantages.*

Le Fort III Osteotomy (Extracranial Approach to the Midface)

Shetye and colleagues set out to examine long-term (10-year) midface skeletal stability and the potential for maxillary growth after extracranial Le Fort III advancements in children with craniosynostosis syndromes.[242] Their study group included 25 children (10 had Crouzon syndrome, 9 had Apert syndrome, and 6 had Pfeiffer syndrome) who underwent extracranial Le Fort III advancement before they were 11 years old (mean, 5.8 years; range, 3.8 to 10.9 years). Two different forms of fixation were used: Group 1's treatment included intraosseous wires, bone grafts, suspension wires, dental splint, and 8 weeks of intermaxillary fixation; Group 2's treatment involved titanium plates and screws, bone grafts, dental splints, and elastics. Good stability of the midface was documented in both groups at 1 year, 5 years, and 10 years. As has been found with previously published studies, no significant horizontal growth occurred in the midface after surgery. The form of fixation used was not a factor (i.e., plate and screw fixation did not increase incidence of growth restriction). The mandible was measured at the pogonion and found to advance 5.72 mm and 7.32 mm at the 5- and 10-year time points, respectively. This study confirms that, when the Le Fort III advancement is carried out at a young age, the occurrence of jaw disharmony with ongoing growth is inevitable and will require further staged reconstruction.

In a second publication, Shetye and colleagues evaluated a larger group of syndromal craniosynostosis patients who also underwent extracranial Le Fort III advancement between the years of 1973 and 2006.[238] Three different stabilization techniques were sequentially used over the study period: Group 1 (n = 20) was treated with intraosseous wires, suspension wires, bone grafts, dental splinting, and 8 weeks of intermaxillary fixation; Group 2 (n = 20) was treated with titanium plates and screws, bone grafts, dental splinting, and elastics; and Group 3 (n = 20) was treated with the extended use of an external DO device during 3 months of healing. The stability of midface advancement was assessed with the use of measurements from 1- and 5-year postoperative lateral cephalometric radiographs. Patients in Groups 1 and 3 showed equal levels of skeletal stability, whereas Group 2 showed slightly less stability at the A point. At the orbitale, all three groups showed similar levels of stability. Interestingly, all three methods of fixation for the extracranial Le Fort III advancements showed good levels of stability. The study also confirmed that all study subjects who were in the mixed dentition demonstrated progressive facial disharmony as a result of ongoing mandibular growth, thereby necessitating further skeletal reconstruction by the late teenage years (i.e., different forms of fixation had no bearing on the incidence of growth restriction).

In the discussion, McCarthy, who was the senior investigator, stated his personal preference for the management of the midface deformity in syndromal craniosynostosis with an extracranial Le Fort III advancement followed by orthognathic surgery. When early Le Fort III advancement is indicated in a growing child, he prefers distraction to standard techniques. According to McCarthy, it is easier to overcorrect the advancement with the use of DO, which is one of his stated objectives for young children (i.e., those who are <11 years old). Standard extracranial Le Fort III advancements with plate and screw fixation and bone grafts are preferred by McCarthy for older children and adults (i.e., those who are >11 years old), because this allows for

reduced treatment time and less patient psychosocial issues (i.e., there is no need to wear an external DO device for 3 months after surgery).

McCarthy and colleagues recently reviewed the long-term midface growth and periorbital/malar (upper midface) aesthetic results in individuals who were born with a craniosynostosis syndrome and who had undergone Le Fort III advancement.[276] The study represented a follow-up period of more than 20 years for four identified patients (one with Apert syndrome and three with Crouzon syndrome) who were 4, 6, 14, and 20 years old at the time of the Le Fort III advancement. Thus, this study represented two young children and two skeletally mature individuals who underwent Le Fort III midface advancement. The authors' review confirmed several points: 1) a Le Fort III advancement carried out during early childhood results in no further horizontal growth of the midface; 2) a Le Fort III advancement carried out during early childhood results in further vertical growth of the midface with clockwise rotation of the mandible; and 3) a Le Fort III advancement carried out in individuals with either Crouzon or Apert syndrome—whether during childhood or adulthood—does not effectively correct the presenting zygomatic, orbital, and nasal malformations. The upper midface aesthetic results as viewed through the overlying soft-tissue envelope (i.e., the eyelid–cheek–malar region) were suboptimal after Le Fort III advancement. Furthermore, with age, the upper midface aesthetic results became even more unfavorable.

McCarthy's findings of continued vertical growth of the midface after Le Fort III osteotomy carried out during early childhood is consistent with the inability to achieve adequate nasal airflow in the operated patient. In addition, even if adequate nasal airflow is accomplished, at least some individuals will have limited masticatory muscle tone. In either case, when a child continues with an open-mouth protrusive tongue posture, hypereruption (i.e., vertical growth) of the maxillary dentition through the alveolar bone with clockwise rotation of the mandible is expected (see Chapter 4). A lack of horizontal growth of the maxilla after either a Le Fort I, Le Fort III, or MB osteotomy is carried out during childhood has been documented by a number of independent investigators.[31,50,75,76,102,103,112,192] This results from both intrinsic growth limitations of the malformation and injury to the sutural growth centers from the osteotomies that are carried out.

Monobloc and Facial Bipartition Osteotomies: Step-by-Step Description of the Surgical Technique

The lack of consensus about the ideal timing and techniques for the management of complex upper midface malformations and deformities in patients with craniosynostosis syndromes reflects not only uncertainty about the potential results with any one approach to treatment but also confusion about how to perform these technically sensitive procedures.

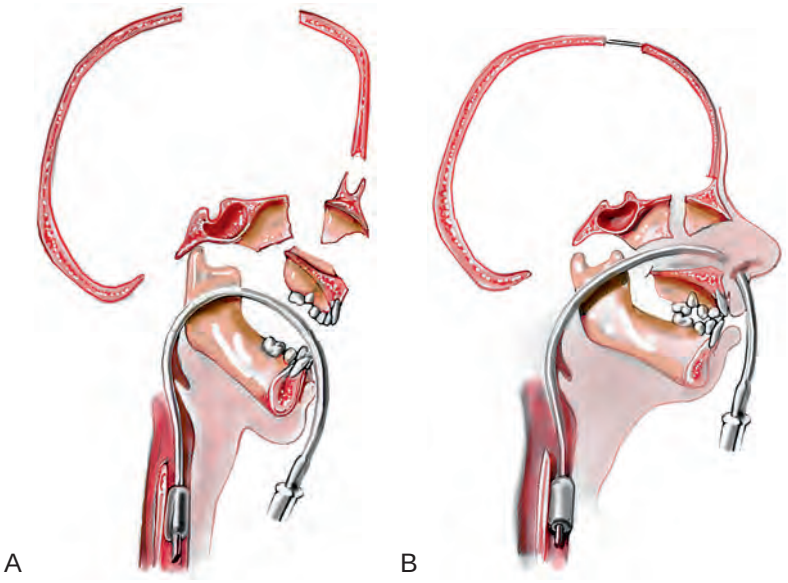
This section provides the surgeon with a step-by-step technical description for the MB and FB osteotomies as this author has routinely performed them. The detailed operative technique is illustrated through the case of a 12-year-old Persian girl who was born with Pfeiffer syndrome and who had never undergone surgery. The patient then underwent FB osteotomies in combination with anterior cranial vault reshaping (see Fig. 30-14). A review of the October 1992 Plastic Surgery Education Foundation Teleplast Conference: Monobloc and Facial Bipartition for Reconstruction of Craniofacial Malformations may serve as an additional educational tool to complete the surgeon's understanding of the technical aspects of the procedures that will be described (Video 15).

Monobloc and Facial Bipartition Osteotomies: Step-by-Step Approach

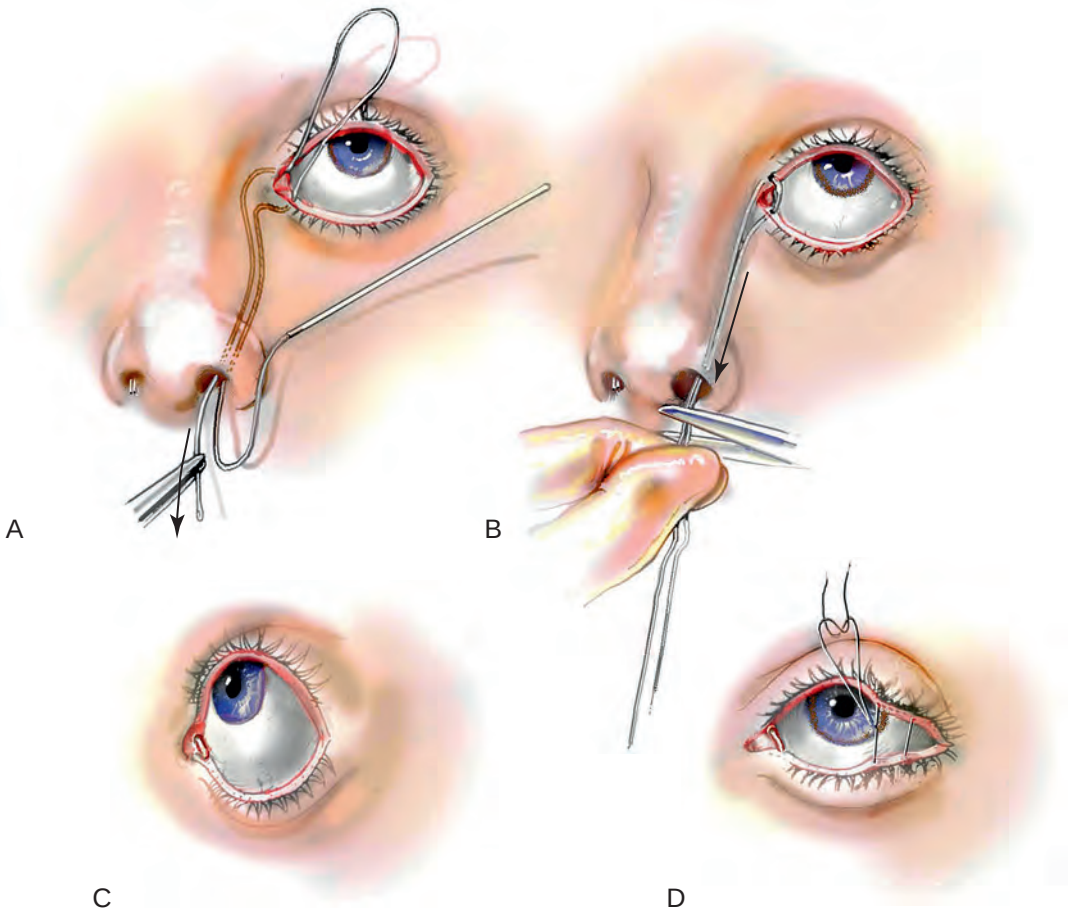
Step 1. Satisfactory airway management in a patient who is undergoing an MB/FB osteotomy is essential. A method that I have used effectively involves an orotracheal tube that is secured adjacent to the cusp edge of the mandibular incisors with a circummandibular wire (Fig. 30-16, *A*). After the MB/FB osteotomies and disimpaction are completed, a nasotracheal tube is placed, and the orotracheal tube is removed (Fig. 30-16, *B*). Through this controlled approach, endotracheal tube injury at the completion of the osteotomies and dislodgement during disimpaction are prevented. In addition, direct contact between the maxillary and mandibular teeth can be achieved for the improved control of the occlusion. The nasotracheal tube remains in place at the end of the procedure to allow for nasal mucosal stenting during the initial postoperative phase. Other approaches to managing the airway have been described and used effectively (e.g., tracheostomy, submental intubation, orotracheal intubation without exchange).

Step 2. When feasible, I recommend the placement of Crawford tubes to protect the nasolacrimal apparatus during surgery (Fig. 30-17). The puncta are dilated, and a probe is inserted through each punctum to confirm entrance into the nose. The Crawford tube is inserted through each punctum and pulled through the nose. Within the nose, the Silastic sheeting is stripped; the tubing is tied in the nose, and the excess is cut in the nose with scissors.

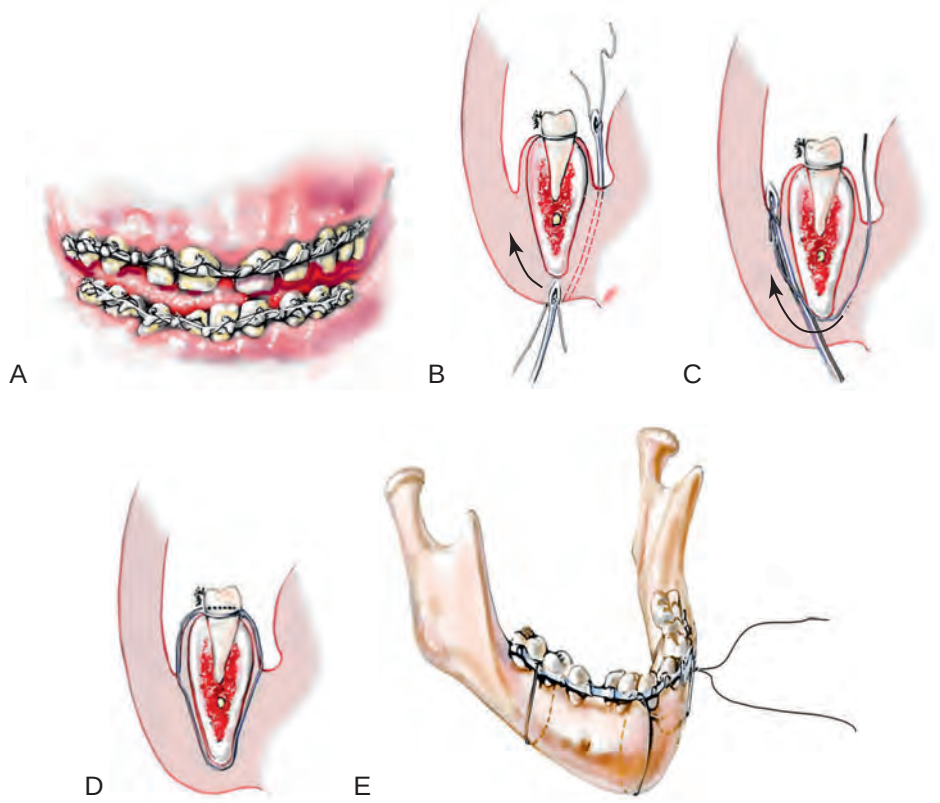
Temporary tarsorrhaphies are placed with 6-0 nylon suture from gray line to gray line just lateral to the pupil of each eye. As an alternative, corneal shields may be used to protect the cornea, but this



• **Figure 30-16 A** and **B,** Step 1. Illustrations of a 12-year-old girl with Pfeiffer syndrome (see Fig. 30-14) before and after facial bipartition. The step-by-step approach for the surgical technique that was carried out is described in the text. *From Posnick JC: Craniofacial dysostosis syndromes: a staged reconstructive approach. In Turvery JA, Vig TWL, Fonseca RJ, eds:* Facial clefts and craniosynostosis: principles and management, *vol 26, Philadelphia, 1995, W.B. Saunders, p 645.*



• **Figure 30-17 A** through **D,** Step 2.



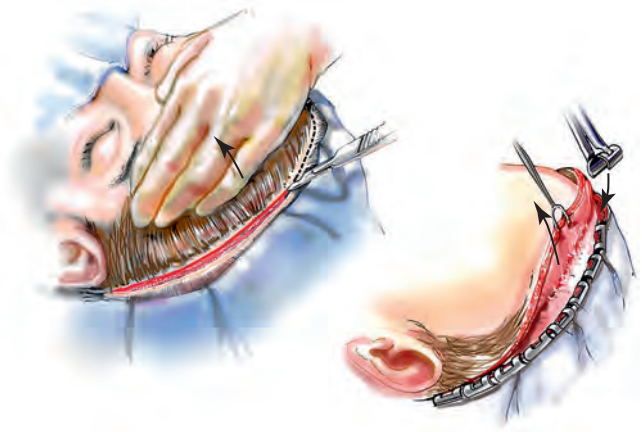
• **Figure 30-18** **A** through **E,** Step 3.

prevents the direct examination of the pupils during surgery.

Step 3. Surgical arch wires are generally applied (Fig. 30-18). A throat pack is placed, and the mouth is cleansed. Erich arch bars are applied to the maxillary and mandibular teeth. Circum-mandibular wires are placed to further stabilize the mandibular arch bar, and the orotracheal tube is secured with a wire to the symphyseal region of the surgical arch bar.

Step 4. The patient is prepared and draped. The patient's head is placed in a Mayfield (horseshoe-shaped) head holder in the neutral neck position. Cleansing of the entire scalp is performed with povidone–iodine (Betadine) soap; the soap is then washed out with sterile water. Next, the application of povidone–iodine solution to the scalp, face, and neck is carried out. The surgical field is draped to expose the neck down to the clavicles; the full face, including the external ears; and the anterior scalp back to the planned incision. The separation of the mouth/nose from the eyes/forehead is achieved with an additional sterile towel drape; this is done to limit the contamination of the intracranial cavity with oral or nasal flora.

Step 5. A coronal (scalp) skin incision is completed (Fig. 30-19). The incision site is postauricular and posterior in the scalp. Other incision modifications



• **Figure 30-19** Step 5.

have been described (e.g., Z-plasty in the temporal regions). Lidocaine with epinephrine is injected to facilitate hemostasis.

Step 6. The anterior scalp flap is then elevated by remaining deep to the superficial layer of the deep temporal fascia over the temporalis muscles; subperiosteal over the mid-forehead region; subperiosteal down the lateral orbital rims; subperiosteal with exposure of the anterior maxilla; subperiosteal for exposure of the zygomatic aches;

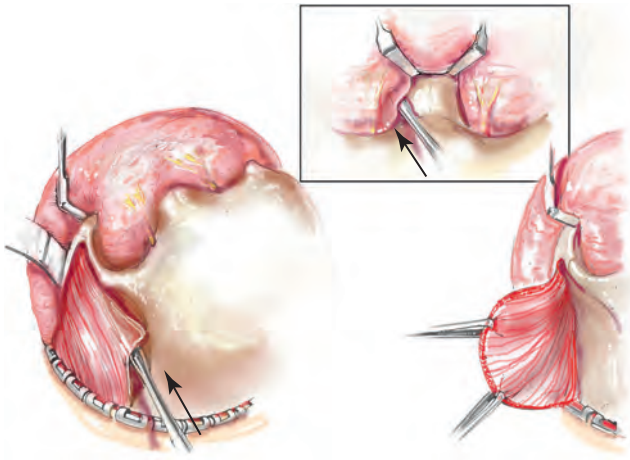
and subperiosteal over the dorsum of the nose. Elevation of the temporalis muscles off of the squamous temporal bones is then carried out (Fig. 30-20).

Step 7. Bifrontal craniotomy is completed (Fig. 30-21, *A*). The craniotomy lines are drawn with a sterile pencil, and bur holes are completed with a perforator as needed. The craniotomies are completed with a craniotome. The frontal bones are separated from the underlying dura and then removed. The frontal and temporal lobes of the brain are adequately retracted to safely accomplish skull base osteotomies. The brain is protected with cottonoid pledgets (Fig. 30-21, *B*).

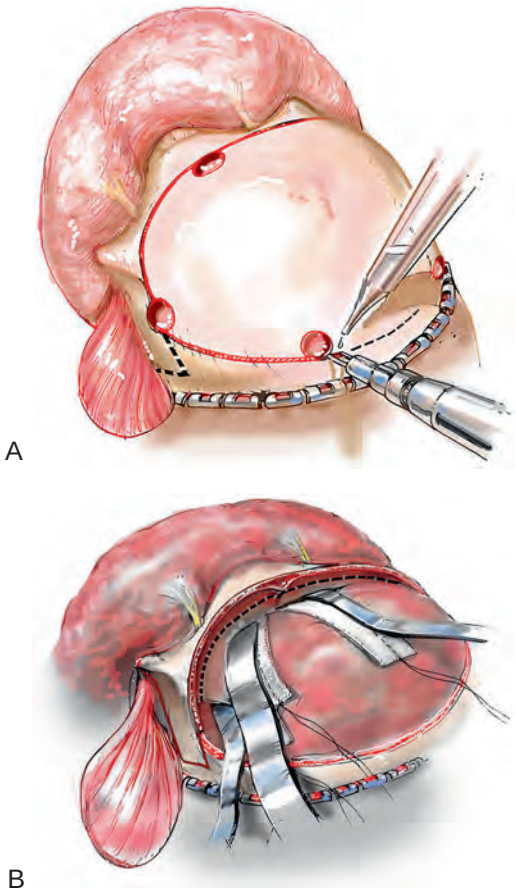
Step 8. Zygomatic arch osteotomies are performed (Fig. 30-22). Retractors are placed, and an osteotomy is completed through the midzygomatic arch on each side with a sagittal (reciprocating) saw.

Step 9. With the use of the sagittal saw, the lateral orbital wall osteotomy is initiated into the inferior orbital fissure. The osteotomy is extended superiorly through the lateral orbital wall (Fig. 30-23).

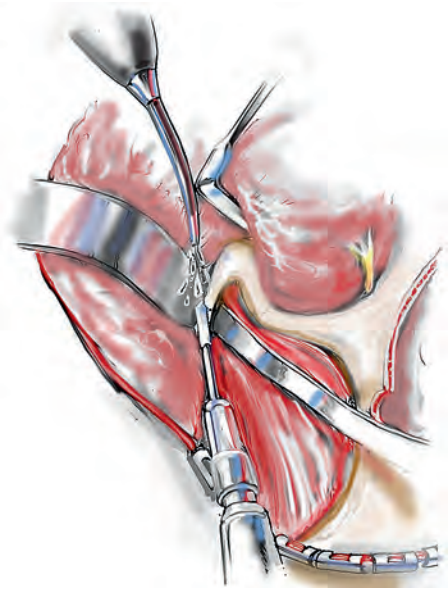
Step 10. With the continued use of the sagittal saw, the lateral tenon extension of the osteotomy through



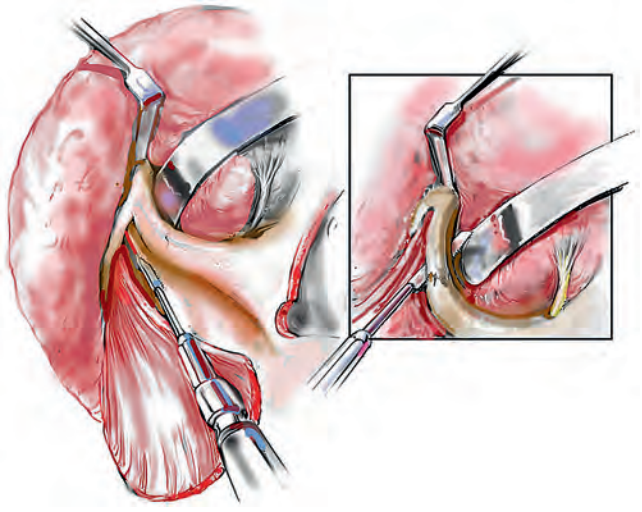
• **Figure 30-20** Step 6.



• **Figure 30-21** **A** and **B,** Step 7, *A* and *B*.



• **Figure 30-22** Step 8.



• **Figure 30-23** Step 9.

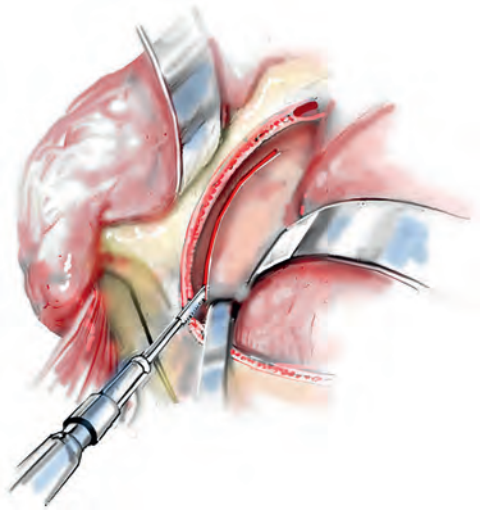
the squamous temporal bone and skull base is carried out (Fig. 30-24).

Step 11. The orbital roof osteotomy is completed with the sagittal saw through the anterior skull base (Fig. 30-25).

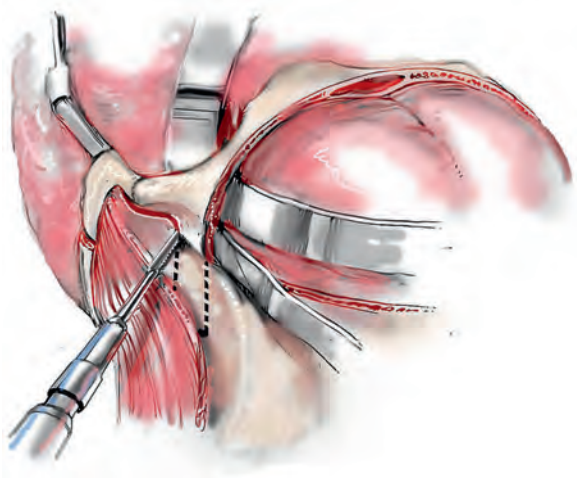
Step 12. The orbital roof osteotomy continues laterally through the sphenoid wing. This osteotomy will join up with the previous tenon extension on each side (Fig. 30-26).

Step 13. A thin chisel placed through the anterior skull base is used to confirm the completion of the sphenoid wing osteotomy and continuity with the tenon extension (Fig. 30-27).

Step 14. With a thin chisel and working through the skull base, the medial orbital wall osteotomy is completed posterior to the medial canthus and nasolacrimal apparatus and inferiorly into the inferior orbital fissure (Fig. 30-28).

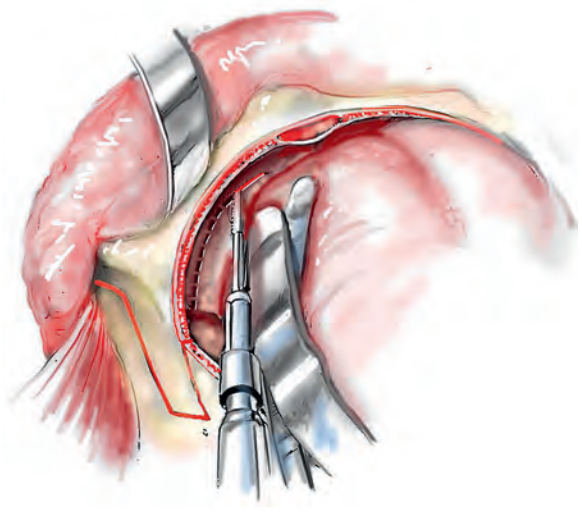


• **Figure 30-26** Step 12.

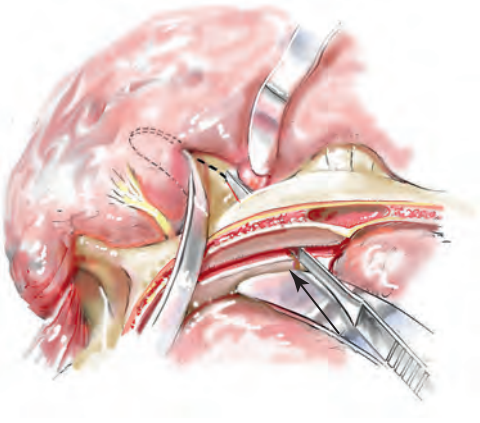


• **Figure 30-24** Step 10.

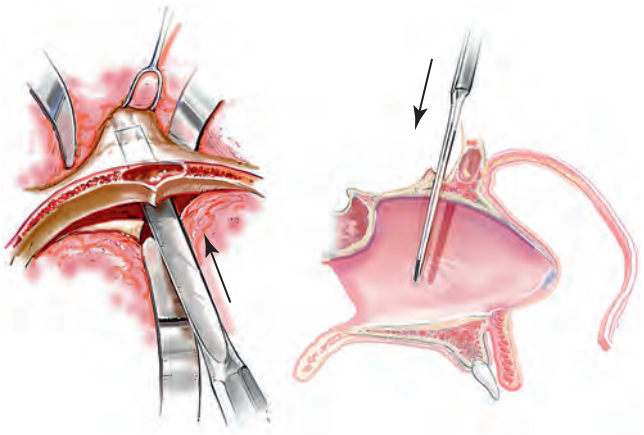
• **Figure 30-27** Step 13.



• **Figure 30-25** Step 11.



• **Figure 30-28** Step 14.



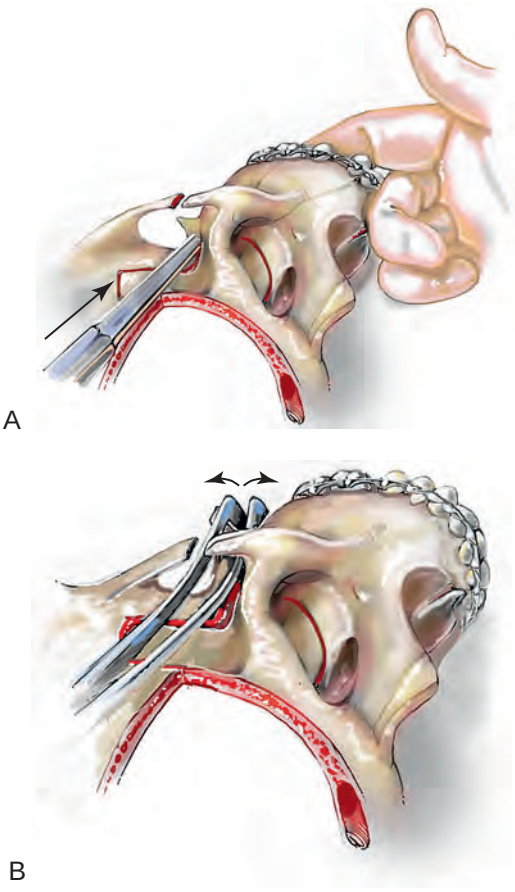
• **Figure 30-29** Step 15.

Step 15. The anterior aspect of the nasal septum is separated from the cranial base. A straight 15-mm wide chisel is placed through the cranial base just anterior to the crista galli and used to complete this osteotomy and to further separate the midface from the base of the skull (Fig. 30-29).

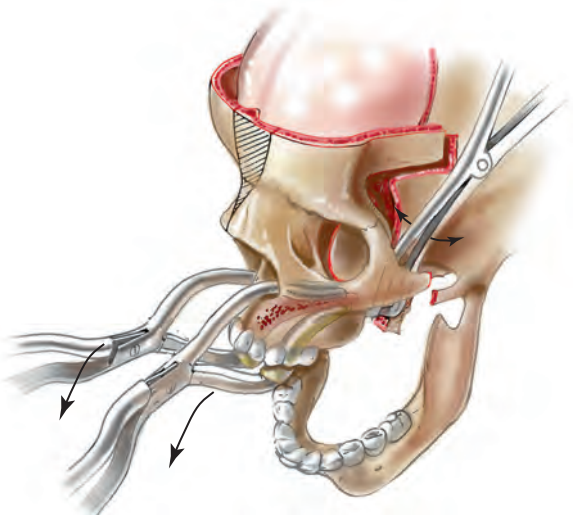
Step 16. The separation of the pterygomaxillary sutures is completed. A long 10-mm wide chisel is placed through the coronal incision and the infratemporal fossa to the pterygomaxillary suture. One double-gloved hand is placed in the patient's mouth, and the other hand is used to place the chisel through the coronal incision and into the infratemporal fossa (Fig. 30-30, *A*). A mallet is then used to separate the pterygomaxillary suture with the chisel. The success of the separation is confirmed with the pterygomaxillary spreader forceps (Fig. 30-30, *B*).

Step 17. The midface (MB) is disimpacted with the use of two nasomaxillary forceps that are placed in the nose and the mouth. Pterygomaxillary spreader forceps are simultaneously placed through the coronal incision on each side. The midface is then disimpacted and stretched forward to confirm adequate advancement at the occlusal level (Fig. 30-31). Next, the endotracheal airway exchange is completed (see Fig. 30-16, *B*). Additional sterile drapes are placed over the scalp and the face and neck regions, and the throat pack is removed. The surgeon places the nasotracheal tube through the nose and into the oropharynx. The anesthesiologist then removes the orotracheal tube and completes the insertion of the nasotracheal tube through the larynx using the direct or GlideScope laryngoscopic technique.

Step 18. For FB, a midnasal osteotomy (i.e., an ostectomy) is completed. Working through the coronal incision, the surgeon marks out the proposed midnasal osteotomy with calipers and a pencil and then completes it with a sagittal saw. When the



• **Figure 30-30** **A** and **B,** Step 16.

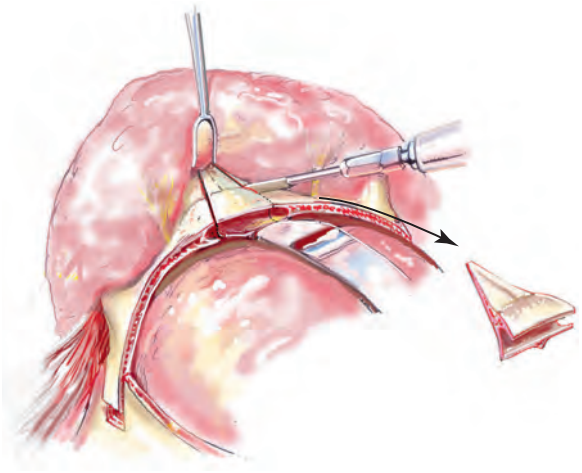


• **Figure 30-31** Step 17.

ostectomy is completed, the removal of portions of the underlying cartilaginous nasal septum is also accomplished (Fig. 30-32).

Step 19. For FB, separate sterile oral instruments are used to split the maxilla into two segments. An intraoral maxillary vestibular incision is made, and this

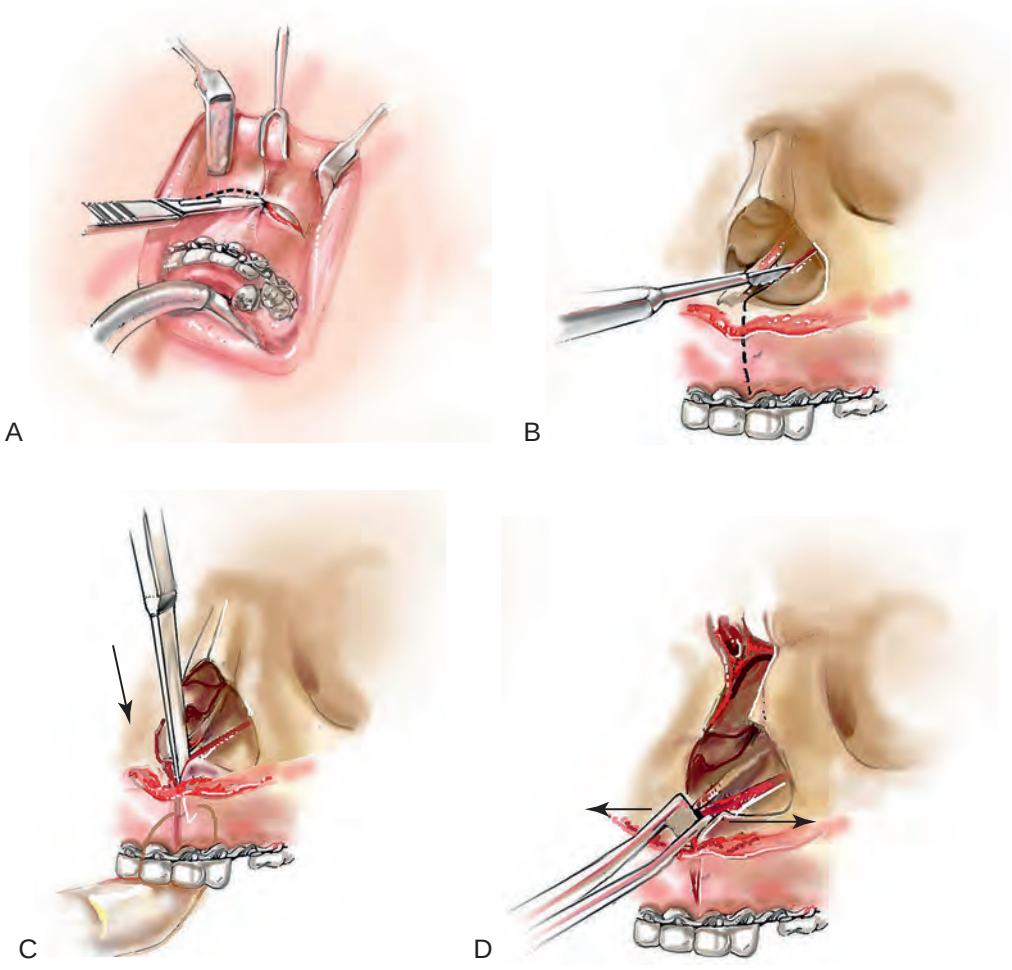
is followed by the subperiosteal exposure of the anterior maxilla, the anterior nasal spine, and the nasal floor (Fig. 30-33, *A*). With a sagittal saw, a midline osteotomy is completed between the central incisors and then parasagittally down the hard palate; the palatal mucosa is left undisturbed (Fig. 30-33, *B*). The segmental separation is completed with a thin 5-mm wide chisel placed between the central incisors (Fig. 30-33, *C*). The Erich arch bar is also cut between the incisors. Further separation of the posterior maxilla is completed with a spreader forceps as needed (Fig. 30-33, *D*). The oral wound is closed, the intraoral instruments are discarded, and fresh gloves are put on the hands.



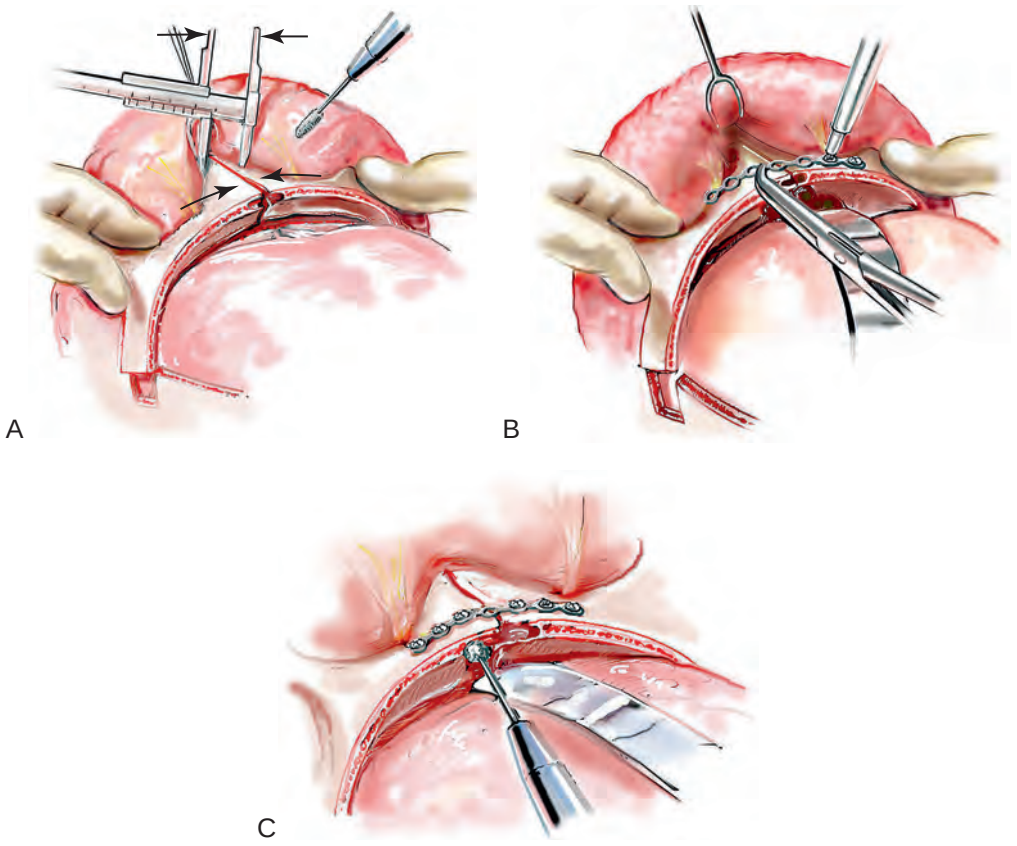
• **Figure 30-32** Step 18.

Step 20. For FB, stabilization of the upper orbits and the nasal bones is completed next (Fig. 30-34, *A, and B*). Repositioning of the facial halves medially with correction of the midface arc of rotation is completed; this will require refinement with a rotary drill (Fig. 30-34, *A*). The upper orbits and the nasal bones are fixed with a titanium plate and screws (Fig. 30-34, *B*). A rotary drill is also used to cranialize the frontal sinus, if needed (Fig. 30-34, *C*).

Step 21. Midface advancement at the level of the maxillary dentition is accomplished (Fig. 30-35). Working through the coronal scalp incision, the primary



• **Figure 30-33 A** through **D,** Step 19.



• **Figure 30-34 A, B,** and **C,** Step 20.

surgeon advances the midface. With the use of separate sterile oral instruments, the assistant to the surgeon wires the jaws together into the planned occlusion.

NOTE: The patient is rarely placed in an ideal occlusion. The mid face advancement at the occlusal level is of secondary importance. The advancement should be based on the most favorable depth of the orbits and position of the zygomas.

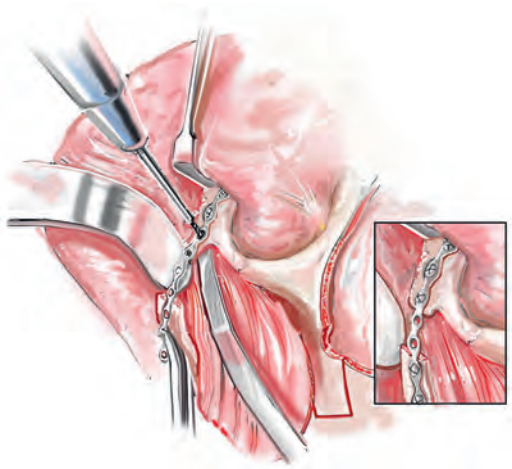
Step 22. Upper midface advancement is established at the zygomatic arches (Fig. 30-36). The amount of advancement at each zygomatic arch is measured with a caliper. A titanium plate is conformed to extend from the anterior maxilla across the arch and surgical gap to the posterior zygoma on each side. The plate is secured with titanium screws.

Step 23. Additional segmental osteotomies of the orbits are often required. Occasionally, the lateral superior orbits have further dysplasia and segmental osteotomies with reshaping for reconstruction is necessary (Fig. 30-37, *A*). If so, the lateral orbital segments are removed with a reciprocating saw.

• **Figure 30-35** Step 21.

Additional segmental orbital osteotomies are then completed with a reciprocating saw (Fig. 30-37, *B*). The lateral orbital rim and superior orbital rim segments are further reshaped with a rotary drill (Fig. 30-37, *C*). The segments are fixed with titanium plates and screws (Fig. 30-37, *D*).

Step 24. Stabilization of the midface advancement at the upper orbital tenon extension is accomplished

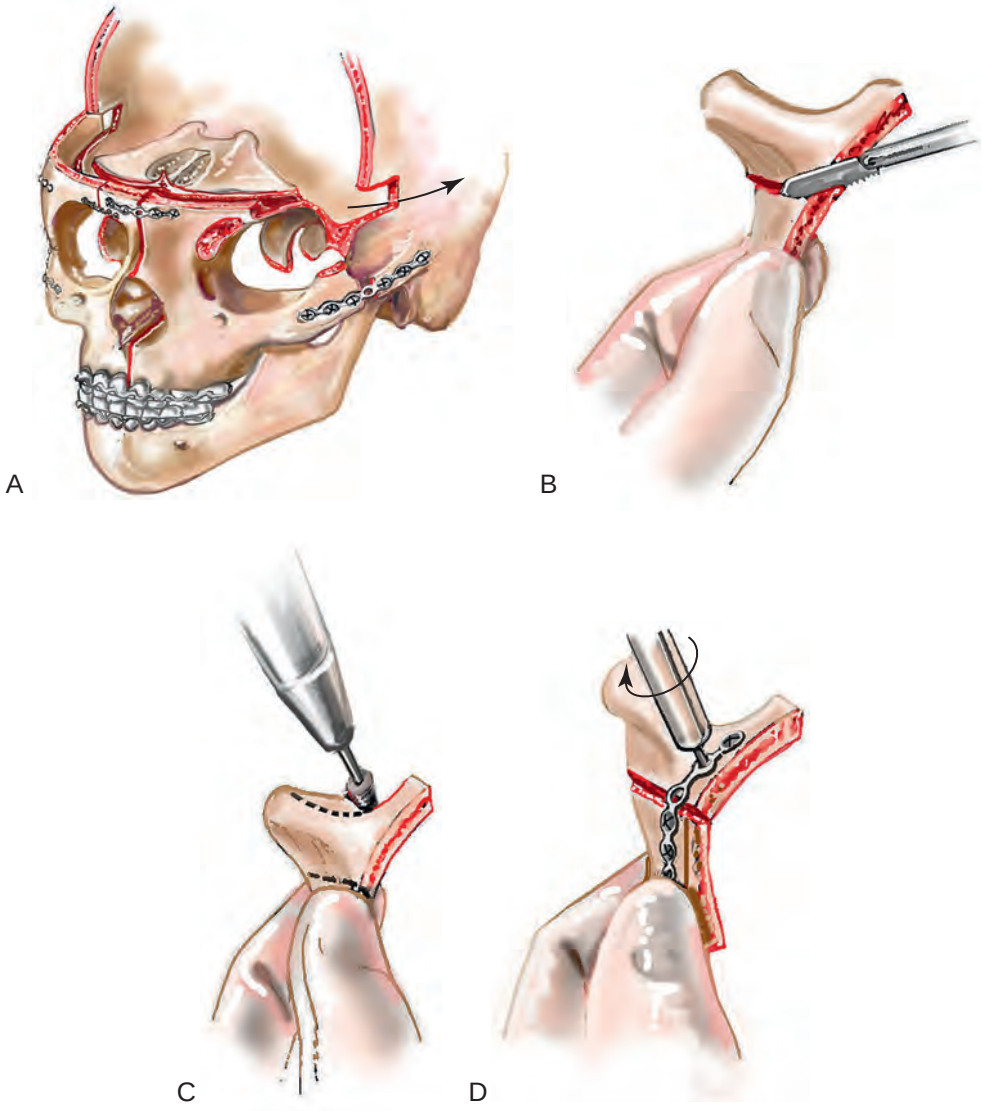


• **Figure 30-36** Step 22.

(Fig. 30-38). The desired advancement is measured with a caliper; a miniplate is adapted to bridge the gap between the tenon extension and the posterior cranial vault. Titanium screws are used for plate stabilization.

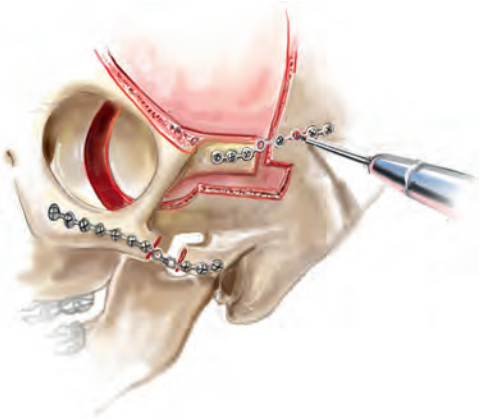
Step 25. Hyperplastic ethmoidal air cells are debrided as needed in patients with orbital hypertelorism (Fig. 30-39). With visualization through the anterior cranial base, rongeurs are used to debride hyperplastic ethmoidal air cells and to reduce midorbital hypertelorism.

Step 26. The opening between the anterior cranial fossa and the nasal cavity is managed (Fig. 30-40, *A* and *B*). The surgeon irrigates and suctions the intranasal cavity through the anterior cranial base exposure. My usual approach is to then apply a

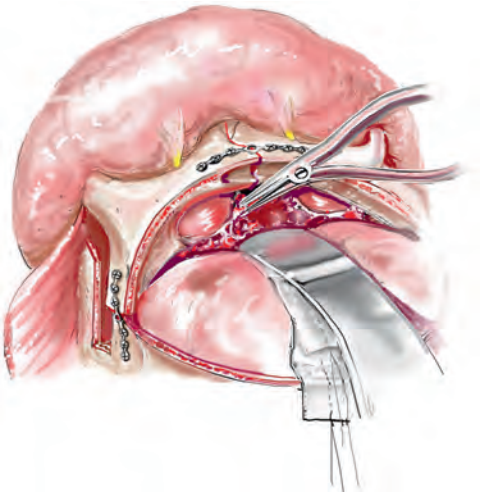


• **Figure 30-37 A** through **D,** Step 23.

sheet of Gelfoam to separate the opening between the two cavities (Fig. 30-40, *A*). I then inject fibrin glue over the Gelfoam to seal the separation (Fig. 30-40, *B*). Other methods of managing the separation between the nasal cavity and the anterior cranial fossa may be used, depending on the clinical circumstances (e.g., cranial bone grafts, soft-tissue flaps).



• **Figure 30-38** Step 24.



• **Figure 30-39** Step 25.

Step 27. The anterior cranial vault is reshaped, advanced, and secured in place (Fig. 30-41, *A, B,* and *C*). With the use of a reciprocating saw, osteotomies of the removed anterior cranial vault are completed (Fig. 30-41, *A*). Rotary drill recontouring is also accomplished to achieve the desired shape (Fig. 30-41, *B*). Split- or full-thickness cranial bone graft is harvested and used as needed to fill in defects, and fixation is accomplished with plates and screws. Split-thickness cranial bone graft is also placed and fixed in the midzygomatic arch segmental defects (Fig. 30-41, *C*).

Step 28. Lateral canthopexies are completed (Fig. 30-42). Two holes are drilled at each new frontozygomatic suture region. The lateral canthi are identified with a skin hook through the coronal incision. A figure-of-eight wire suture is placed through each lateral canthus through the coronal incision. Each lateral canthus is fixed by passing the wire through the drill holes in the frontozygomatic suture.

Step 29. Each temporalis muscle is resecured to bone (Fig. 30-43). The temporalis muscles are repositioned anteriorly and secured to the lateral orbital rims and the temporal bones with interrupted sutures.

Step 30. The scalp wound is closed (Fig. 30-44). Suction drains are placed through the posterior scalp flap; one is placed on each side. One drain is placed under the anterior flap, and the other is placed below the posterior flap. The galea closure is completed with interrupted sutures, and the skin layer closure is completed with staples or resorbable sutures in accordance with surgeon preference.

An overview of the skeletal morphology is shown before (Fig. 30-45, *A*) and after (Fig. 30-45, *B*) Facial Bipartition (FB) osteotomies and anterior cranial vault reshaping, repositioning, and stabilization. The locations of the proposed osteotomies are indicated.

Staging of Reconstruction for Crouzon Syndrome

Primary Brain Decompression: Cranio–Orbital Reshaping during Infancy

The initial surgery for a child with a craniosynostosis syndrome generally requires cranial suture release, simultaneous anterior cranial vault and upper orbital osteotomies, and reshaping and advancement for brain decompression.[200,203,205,216,274] There continues to be a search for minimally invasive approaches to the surgical decompression of the brain in the infant with syndromal craniosynostosis; the goal is to limit morbidity while achieving morphologic correction or at least improvement. Current minimally invasive techniques that are under consideration include endoscopic suture release; spring-mediated cranioplasty; and DO procedures. These techniques must be compared with the standard "open" approach of cranio–orbital reshaping carried out by an experienced craniofacial team; this is described later in this chapter. In addition, the preferred timing for brain decompression (i.e., <6 months; 6 to 12 months, >12 months) remains undetermined. Current studies support the 6- to 12-month time frame for first-stage brain decompression whenever feasible. Operating at an earlier age is more likely to result in the need for early reoperation and may involve increased perioperative risk.

In the infant with Crouzon syndrome who presents with bicoronal synostosis, my preference is to carry out the primary cranio–orbital reshaping when the child is 9 to 12 months old unless clear signs of increased intracranial pressure are identified earlier during his or her life.[153,200,203,205,216] The standard technique of reshaping of the upper three quarters of the orbits and the tenon extensions is geared toward decreasing the bitemporal and anterior cranial base width while achieving anteroposterior advancement. This

increases the depth of the anterior cranial base and the upper orbits with at least some improvement of ocular proptosis. The anterior cranial vault is then reconstructed in accordance with the patient's morphologic needs. The goals at this stage are to provide increased space in the anterior fossa for the brain; to increase orbital volume for better eye protection; and to improve the morphology of the forehead and the upper orbits. By allowing additional growth to occur before surgery (i.e., by waiting until the child is 9 to 12 months old), the reconstructed cranial vault and the upper orbital shape are better maintained with less need for repeat craniotomy procedures during early childhood.

Further Craniotomy for Brain Decompression during Childhood

After the initial suture release and the reshaping of the cranio–orbital region during infancy, the child is observed clinically at set intervals by the craniofacial surgeon, the pediatric neurosurgeon, the pediatric ophthalmologist, and the developmental specialist; he or she also undergoes interval CT scanning. Should signs of increased intracranial pressure develop, urgent brain decompression via further cranial vault expansion and reshaping is performed.[64,87,137,200,203,205,216] When increased intracranial pressure occurs, the suspected location of brain compression influences the region of the skull for which further expansion and reshaping is planned. If progressive brain compression is judged to be anterior, then additional forehead and upper orbital osteotomies with reshaping for expansion are carried out. The technique is similar to that described earlier in this chapter. If the problem is posterior, then expansion of the occipital region with the patient in the prone position is required. The repeat craniotomy is often complicated by brittle irregular cortical bone, which lacks a diploic space and which may contain sharp spicules that pierce the dura; by the presence of previously placed fixation hardware in the operative field; and by convoluted thin dura that is compressed against or herniated into the inner table of the skull. This results in a greater potential for dural tears during the calvarectomy than would normally occur during a primary procedure.

Management of the Upper Midface Deformity during Childhood

The approach selected to manage upper midface deficiencies and anomalies and residual cranial vault dysplasia should depend on the extent and location of dysmorphology.[200,203,205] A main objective of this phase of reconstruction is to normalize the orbits, the zygomas, and the cranial vault. The correction of the maxillomandibular deformity will require orthognathic surgery that includes a separate Le Fort I osteotomy. The selection of either an MB osteotomy (with or without additional orbital segmentation), an FB osteotomy (with or without additional orbital segmentation), or an extracranial Le Fort III osteotomy to manage the basic horizontal, transverse, and vertical upper and midface deficiencies and anomalies will depend on the original malformation, the previous procedures that have been carried out, and the effects of ongoing growth. The final reconstruction of the upper midface deformities in a patient with Crouzon syndrome can be managed when he or she is as young as 7 to 10 years old. (See previous sections in this chapter concerning upper midface reconstruction options).

Orthognathic Procedures to Achieve Facial Balance, an Improved Airway, and Definitive Occlusal Correction

Although the mandible has a normal basic growth potential in a patient with Crouzon syndrome, the maxilla does not. An Angle class III malocclusion caused by deficient maxillary growth is to be expected. A segmented Le Fort I osteotomy for maxillary horizontal advancement, transverse widening, and vertical adjustment is generally required in combination with an osseous genioplasty (vertical reduction and horizontal advancement) to further correct the lower face dysmorphology.[200,203,205] Secondary deformity of the mandible is also frequent and requires simultaneous sagittal ramus osteotomies. If correction of chronic nasal obstruction is required, then septoplasty, inferior turbinate reduction, the widening of the pyriform rims, and nasal floor recontouring are simultaneously completed (see Chapter 10). The definitive orthognathic and intranasal procedures are carried out in conjunction with orthodontic treatment that is planned for completion at the time of early skeletal maturity (i.e., ≈13 to 15 years in girls and ≈14 to 16 years in boys).

Assessment of Results in the Patient with Crouzon Syndrome

CT scans have provided the quantitative assessment of baseline craniofacial abnormalities in patients with Crouzon syndrome as well as of surgical results after first-stage cranio–orbital reconstruction.[216] The purposes of the quantitative assessment of the craniofacial complex—whether by CT scan or by anthropometric, cephalometric, or model analysis—are to help predict growth patterns, to confirm or refute clinical impressions, to help with treatment planning, and to provide a framework for the objective assessment of the immediate and long-term reconstructive results.

Quantitative Assessment of Presenting Crouzon Deformity and Surgical Results on the Basis of Computed Tomography Scan Analysis after First-Stage Cranio–Orbital Reconstruction

Waitzman and colleagues developed a method of analysis based on CT scan measurements and that allows for a quantitative assessment of the upper and midface skeleton

in both the horizontal and transverse planes.[272,273] This method of quantitative CT scan analysis was used to document the differences in the cranio–orbito–zygomatic region between children with Crouzon syndrome who had not yet undergone reconstruction and age-matched controls.[29] Morphologic results that were achieved in those children 1 year after undergoing standard suture release and anterior cranial vault and upper orbital procedures to reshape these regions were also evaluated.[216]

The preoperative CT scan measurements of the children with untreated Crouzon syndrome confirmed a widened anterior cranial vault at 108% of normal and a cranial length that averaged only 92% of normal.[29] In comparison with age-matched controls, orbital measurements revealed a widened anterior interorbital width at 122% of normal, an increased intertemporal width at 121% of normal, globe protrusion at 119% of normal, and a short medial orbital wall length at only 86% of normal. The distance between the zygomatic buttresses and the interarch widths were found to be increased at 106% and 103% of normal, respectively. The zygomatic arch lengths were substantially shortened at only 87% of the values of age-matched controls. These findings confirmed clinical observations of brachycephalic anterior cranial vaults with shallow and frequently hyperteloric orbits and globe proptosis. In general, the upper midface in patients with Crouzon syndrome is horizontally retrusive and transversely wide, which is reflected in wide and shortened zygomas. The same quantitative CT scan assessment was carried out in the children with Crouzon syndrome more than 1 year after they underwent anterior cranial vault and upper orbital osteotomies with reshaping to compare their values to the new age-matched control values.[216] No significant improvement in the cranio–orbito–zygomatic measurements was demonstrated.

Quantitative Intracranial Volume Measurements Before and After Cranio–Orbital Reshaping in Children with Crouzon Syndrome

In a previous study, the intracranial volumes in children with Crouzon syndrome before and after standard cranio–orbital reshaping procedures was documents.[209] The intracranial volumes were also compared with those of an age- and gender-matched cohort, and the rate of cranial expansion with growth was reviewed. The study included 13 children who presented sequentially with Crouzon syndrome and who subsequently underwent a standard first-stage cranio–orbital reconstruction by the author (Posnick) in conjunction with a pediatric neurosurgeon. The average age at the time of operation was 13 months (range, 6 to 46 months). Postoperative clinical follow up ranged from 12 to 60 months at the time of the study's completion. Of the children with Crouzon syndrome who were evaluated preoperatively, 12 out of 13 had intracranial volume values that were greater than the mean. When comparing postoperative volumes with the normative data, all 13 maintained volumes that were at or greater than the mean. When reviewing the cranial capacity of each patient with Crouzon syndrome over time, 5 of the 13 patients approximated the normal growth curve, whereas 6 of the 13 patients exceeded it. According to the findings of the study, for the majority of children who were born with Crouzon syndrome, the cranial capacity will exceed the mean early during life and expand at a rapid rate in conjunction with cranio–orbital decompression and reconstruction. The biologic explanation for these unexpected findings remains unclear. It should be noted that other researchers have studied the intracranial volume of children who were born with craniosynostosis.[18,20,21,24,60,64,67,73,80,85-87,93,137,140,141,210,246,247]

Quantitative Assessment of Presenting Deformity during the Mixed Dentition in Children with Crouzon Syndrome and Surgical Results after Monobloc Osteotomy on the Basis of Computed Tomography Scan Analysis

During their middle childhood years, a group of children with Crouzon syndrome were assessed via quantitative CT scan measurements. They were found to have cranial vault lengths that averaged only 87% of the values of the age-matched norms. The medial orbital walls were horizontally short at 87% of normal, whereas the extent of globe protrusion was excessive at 134% of age-matched norms. The zygomatic arch lengths averaged only 84% of normal. These findings confirmed horizontal anteroposterior deficiency of the upper face and the midface.

After they underwent MB osteotomies in combination with anterior cranial vault reshaping and advancement carried out through an intracranial approach, the children's cranio–orbito–zygomatic measurements were re-evaluated. The mean cranial length that was initially achieved after MB osteotomy was 98%, and at 1 year it was 92% of the control value. As compared with age-matched controls, the orbital measurements reflected improvements in both the midorbital hypertelorism (the mid-interorbital width was 97% initially after operation and 102% at 1 year), and the orbital proptosis (early after surgery, their values were 86% of the values for age-matched normal children; they were 92% at 1 year). The medial orbital wall length initially normalized at 101% and later at 97% of normal values. The zygomatic arch length initially corrected at 106% and later to 101% of normal.

Staging of Reconstruction for Apert Syndrome

Primary Brain Decompression: Cranio–Orbital Reshaping during Infancy

The initial craniofacial procedure for patients with Apert syndrome generally includes cranial suture release as well as simultaneous anterior cranial vault and upper three-quarter orbital osteotomies, with reshaping and advancement for brain decompression [202] This author's preference is to carry out these procedures when the child is 9 to 12 months old, unless signs of increased intracranial pressure are identified earlier during the child's life. The main goals at this stage

are to decompress the brain by providing increased space in the anterior cranial vault and to increase the orbital volume for improved eye protection. The fronto–orbital surgical technique is similar to that described for Crouzon syndrome (see the section about Crouzon syndrome earlier in this chapter).

Further Craniotomy for Brain Decompression during Childhood

As described previously for Crouzon syndrome, the initial suture release, brain decompression, and cranio–orbital reshaping are carried out during infancy (i.e., 9 to 12 months of age).[202] The child is observed clinically at intervals by the craniofacial surgeon, the pediatric neurosurgeon, the pediatric ophthalmologist, and the developmental pediatrician, and interval CT scanning is also performed. Should signs of increased intracranial pressure develop, further brain decompression with reshaping of the cranial vault to expand the intracranial volume is performed. In patients with Apert syndrome, the posterior cranial vault more commonly requires expansion at this stage. The technique is similar to what has been previously described (see the section about Crouzon syndrome earlier in this chapter).

Management of the Upper Midface Deformity during Childhood

For almost all patients with Apert syndrome, facial bipartition osteotomies in combination with further cranial vault reshaping allow for a better correction of the dysmorphology than can be achieved through any other upper midface procedure (i.e., MB or Le Fort III).[202] When using FB osteotomies, the correction of the concave midface arc of rotation is also possible. This further reduces the stigmata of the "flat, wide, and retrusive" facial appearance associated with Apert syndrome. The FB allows the orbits and the zygomas as units to shift to the midline (i.e., correction of hypertelorism) while the maxillary arch is simultaneously widened (i.e., relief of the V-shaped upper midface). Horizontal advancement of the reassembled upper midface complex is then possible to improve orbital depth and zygomatic length. The forehead is generally flat, tall, and retruded, with a constricting band just above the supraorbital ridge. The reshaping of the anterior cranial vault is also simultaneously carried out. A Le Fort III osteotomy is virtually never adequate for an ideal correction of the residual upper midface anomalies documented among patients with Apert syndrome (see earlier section in this chapter concerning upper midface reconstruction options).

Orthognathic Procedures to Achieve Facial Balance, an Improved Airway, and Definitive Occlusal Correction

The mandible has normal basic growth potential in patients with Apert syndrome, but it is generally secondarily deformed. The extent of maxillary deficiency will result in an Angle Class III anterior open-bite malocclusion. A segmented Le Fort I osteotomy is required for horizontal advancement, transverse widening, and vertical adjustment. This is often in combination with an osseous genioplasty and sagittal split ramus osteotomies of the mandible. Septoplasty and inferior turbinate reduction are generally carried out to improve nasal breathing, and the recontouring of the nasal floor and the pyriform rims is also required (see Chapter 10). The definitive orthognathic and intranasal surgery is carried out in conjunction with orthodontic treatment and planned for completion at the time of early skeletal maturity (i.e., ≈13 to 15 years of age).[202]

Assessment of Results in the Patient with Apert Syndrome

Quantitative Assessment of Presenting Apert Deformity and Surgical Results on the Basis of Computed Tomography Scan Analysis after First-Stage Cranio–Orbital Reconstruction

In a previously published study, a method of quantitative CT scan analysis was applied to document the differences in the cranio–orbito–zygomatic region between children with Apert syndrome who had not been operated on and age-matched controls.[29] Eight consecutive infants and young children with Apert syndrome who underwent a standard cranio–orbital procedure by a single craniofacial surgeon (Posnick) in conjunction with one of three pediatric neurosurgeons over a 4-year period were reviewed 1 year after surgery.[217] The series included seven girls and one boy, with an average age at surgery of 12 months (range, 9 to 23 months). The average postoperative follow-up period was 34 months (range, 12 to 48 months) at the close of the study. Preoperative and postoperative (>1 year) CT scans were compared with those of age-matched controls, and percentages of normal were then compared for significant differences. Two of the children had clear evidence of hydrocephalus and required ventriculoperitoneal shunting before the cranio–orbital reconstruction at 3 and 5 months of age. A third child had mildly increased ventricular size, but clinical correlation did not suggest the need for shunting.

Significant preoperative morphologic findings included a wide anterior cranial vault at 110% of normal, a maximum cranial length that averaged only 90% of normal, a substantially widened anterior interorbital width at 117% of normal, an increased lateral interorbital distance at 112% of normal, and a widened bitemporal width at 122% of normal.[217] Globe protrusion was significant at 121% of normal, and the medial orbital wall length was less than normal at 92%. In the upper midface zygomatic region, both the width between the zygomatic buttresses and the interarch width were found to be increased at 109% of normal, whereas the zygomatic arch lengths were substantially shortened at 79% of normal. The measurements confirmed the clinical observations of brachycephalic and

hyperteloric anterior cranial vaults, orbits, and zygomas accompanied by globe proptosis and midface deficiency. Results of surgical reconstruction as documented by CT scan measurements demonstrated that, at more than 1 year after surgery, none of the craniofacial measurements had significantly improved ($P < .05$) as compared with those of the new age-matched controls.

Quantitative CT scan measurements of the cranio–orbito–zygomatic region confirmed the clinical findings in the unoperated children to be brachycephalic anterior cranial vaults and upper face hypertelorism of the orbits and the zygomas,) with ocular proptosis and a flat midface.[217] It was found that cranial vault and upper orbital reshaping before 1 year of age does not achieve or maintain a corrected shape in the craniofacial skeleton in children with Apert syndrome. Although the cranio–orbito–zygomatic dysmorphology did not worsen when analyzed at least 1 year after surgery, values remained far from those of the new age-matched controls, thereby confirming the need for a staged reconstructive approach.

Quantitative Intracranial Volume Measurements Before and After Cranio–Orbital Reshaping in Children with Apert Syndrome

In published studies, a proven method for obtaining intracranial volumes with the use of CT scan measurement was applied to a consecutive series of children with Apert syndrome before any craniofacial procedures were performed.[209] A standard cranio–orbital operation was performed for each child, and this was followed by longitudinal follow up and the remeasurement of the intracranial volume at least 1 year later. The patients' intracranial volumes were also compared with those of an age-matched cohort, and each patient's cranial growth velocity was reviewed. The study included six girls and two boys with an average age at operation of 12 months (range, 9 to 23 months). The average postoperative follow-up duration at the close of the study was 34 months (range, 12 to 48 months).[209]

Preoperative intracranial volume in the patients with Apert syndrome ranged from 393 mL in a 2-month-old girl to 1715 mL in a 28-month-old girl.[209] A comparison of the preoperative intracranial volume in patients with Apert syndrome with those of the age- and gender-matched cohort group showed that six of the eight patients had values of at least two standard deviations above the mean. Interestingly, the other two were infants who underwent ventriculoperitoneal shunting for hydrocephalus earlier in life. Their measured preoperative intracranial volumes were two standard deviations below the mean. When the patients' postoperative intracranial volumes were compared with those of the cohort group, all eight achieved values of at least two standard deviations above the mean. The majority of the measured preoperative and postoperative intracranial volume values of the patients with Apert syndrome followed a growth curve that greatly exceeded the rate expected for normal children. In three of the patients, cranial vault growth velocity seemed to match closely that expected for a normal child but with a starting point determined by their preoperative values.

The findings confirmed that untreated patients with Apert syndrome are generally macrocephalic early during their lives, that standard cranio–orbital procedures carried out during childhood do not alter this trend, and that continued cranial volume expansion often exceeds the mean. The ability to develop "normal" intracranial volume standards and to identify variations from normal in specific syndromes and in individual patients before and after surgery continues to be elusive.[18,20,21,24,60,73,80,85,86,93,96,140,141,210,246,247]

Quantitative Assessment of Presenting Deformity during the Mixed Dentition in Children with Apert Syndrome and Surgical Results after Facial Bipartition Osteotomy on the Basis of Computed Tomography Scan Analysis

In published studies, children with Apert syndrome were assessed during their middle childhood years with the use of quantitative CT scan measurements.[220] Many of these children's measurements varied from normal as compared with those of age-matched controls. The orbital measurements showed a substantially increased anterior interorbital width (123% of normal), an increased mid-interorbital width (122% of normal), and an increased intertemporal width (126% of normal). The globe protrusion beyond the sagittal plane of the lateral orbital walls was excessive (142% of normal). There was also a short medial orbital wall length (85% of normal). The width between the lateral orbital walls was excessive at 111% of normal. Zygomatic arch lengths were substantially shortened at 83% of normal.

After undergoing FB osteotomies with three-dimensional repositioning in combination with cranial vault reshaping, CT scan measurements were again taken both early after the operation and 1 year later.[220] An analysis of the measurements showed an improvement toward the normal range. As compared with the values of age-matched controls, the orbital measurements reflected the correction of the hypertelorism; the anterior interorbital width early after operation was 106% of normal and later 105% of normal. The mid-interorbital width initially improved to 106% of normal and later to 100% of normal. The width between the lateral orbital walls stabilized at 108% of normal, and the intertemporal width was 115% of normal, which was an improvement over the preoperative value of 126% of normal. The zygomatic arch length was initially overcorrected at 110% of normal and then stabilized at 103% of normal.

Further studies were carried out to evaluate the presence of extradural (retrofrontal) dead space after the FB osteotomy to reconstruct the upper midface deformity associated with Apert syndrome.[208] Seven patients with Apert syndrome (mean age, 8 years) underwent FB osteotomies with advancement. Extradural (retrofrontal) dead space was measured from a reproducible axial CT scan slice for each patient at standard postoperative intervals (1 to 2 weeks, 6 to 8 weeks, and 1 year). An initial extradural (retrofrontal) dead space was identified early after surgery in each patient.

There was good resolution of the dead space by the 6- to 8-week postoperative interval through expansion of the dura and the frontal lobes of the brain. The dead space was confirmed to be closed in all patients at the 1-year postoperative interval. The morbidity of the same consecutive series of patients was then reviewed. For the seven children, there were no deaths, cardiopulmonary sequelae, injuries to the brain or eyes, new seizure activity, or central nervous system problems.

Conclusions

The preferred approach to the management of the individual with a craniosynostosis syndrome is to stage reconstruction to coincide with craniofacial growth patterns, visceral function (e.g., cognitive, vision, breathing, swallowing, speech, chewing, hearing), and psychosocial needs. The recognition of the advantages of a staged approach to reconstruction serves to clarify the objectives of each phase of treatment for the surgeons, the craniofacial team, and the family. By continuing to define a rationale for the timing, techniques, and extent of intervention and then objectively evaluating both head and neck function and morphologic (aesthetic) outcomes, the quality of life for children who are born with craniosynostosis syndromes will improve.

Selected Complex Malformations that Frequently Require Maxillofacial Reconstruction: Evaluation & Treatment

JEFFREY C. POSNICK, DMD, MD

- Klippel–Feil Anomaly
- Down Syndrome (Trisomy 21 Syndrome)
- Neurofibromatosis
- Hemihyperplasia of the Face
- Vascular Malformations
- Velocardiofacial Syndrome
- Conclusions

More than 400 syndromes and anomalies produce a spectrum of head and neck dysfunctions and facial disproportions within the maxillofacial region. Each syndrome type and its presenting set of anomalies will be unique, with individual variations. Developing an appreciation for the complexity of how these patients present is essential to providing thoughtful counsel regarding the timing and techniques of maxillofacial reconstruction and orthodontic care. In this chapter, only a few of the more frequently encountered syndromes are reviewed; suggestions are given for their reconstruction.

Klippel–Feil Anomaly

Background

The Klippel–Feil anomaly (KFA) is characterized by the congenital fusion of two or more cervical vertebrae. In its most severe form, there is massive cervical vertebral fusion with a short neck, limited head movement, and a low posterior hairline.[2,12,15,21,23,29,37,39,55] Gorlin and Cohen have pointed out that the term *vertebral fusion* is not accurate because this condition results from the failure of the normal segmentation process.[24] Vertebral fusion can be traced to the third embryonic week when the segmentation of the mesodermal somites normally takes place.

KFA was described as early as the 16th century, and similar anatomic findings in the second and third cervical vertebrae have been found in an Egyptian mummy that has been dated to be from about 500 B.C. In 1912, Maurice Klippel and Andre Feil described the postmortem findings of a 46-year-old French tailor who had a short, immobile neck with massive fusion of cervical and upper thoracic vertebrae.[34] In 1919, Feil added reports of 13 additional patients, 12 of whose cases had been reported previously.

In 1967, Gunderson and colleagues categorized KFA in accordance with three morphologic types of cervical vertebral fusion.[27] Type I consists of the massive fusion of many cervical and upper thoracic vertebrae into bony locks. Type II involves fusion at only one or two interspaces. Type III comprises both cervical fusion and lower thoracic or lumbar fusion.

It is important to remember that KFA is morphologically and etiologically heterogeneous. This was further documented by Gunderson, who used Feil's classification system to review inheritance patterns.[28] Type I cases have almost all been sporadic, with a female predilection. Type II is transmitted as an autosomal dominant disorder. For Type III, an autosomal recessive mode of inheritance has been suggested.

Various authors differ with regard to their interpretation of what constitutes KFA.[9,61-63] A malformation with the triad of a short neck, a low posterior hairline, and a painless restriction of cervical motion characterizes just over 50% of patients. The functional limitation of the neck range of motion is the most consistent finding. Despite frequent

sparing of the atlanto–axial joint, rotation is typically impaired more than flexion or extension is, with the latter exhibiting a range of more than 90 degrees, even with only one open disc space.

With the severe form of KFA (Type I deformity), there is massive cervical vertebral fusion, and the head seems to sit directly on the thorax, without any interposition of the neck. The flared trapezius muscles extend from the mastoid areas to the shoulders, which produces a pterygium-like effect. Posteriorly, the hairline extends to the shoulders. Cervical foreshortening (rather than overgrowth of the scalp) displaces the hairline and is accompanied by webbing of the neck.

Diverse ocular anomalies are frequently found, with the impairment of extraocular movement being the most frequent.[57]Convergent strabismus and, less commonly, horizontal nystagmuses are seen. From 25% to as many as 50% of affected children exhibit hearing loss that may be sensorineural, mixed, or conductive.[11,16,39,51,60,64] Clefting of the secondary palate is present in 15% to 20% of patients.[10,58,59] The combination of hearing loss and cleft palate explains the hypernasality that has been documented in approximately 15% to 20% of patients with KFA. Congenital heart defects occur in 4.2% of patients, which is in stark contrast with the prevalence of 0.6% among all live births in the general population.[50] Ventricular septal defect is the most common heart anomaly documented,[43] and vascular anomalies may also occur.[5,6] Congenital urinary anomalies are a frequent finding, with unilateral renal agenesis occurring in 28% of patients.[14] Genital anomalies (e.g., vaginal agenesis) also occur at a higher frequency in these patients than they do in the general population.[40,42] Neurologic disturbances that consist of involuntary dyskinesis, spasticity or hyperreflexia, syringomyelia, syringobulbia, disc protrusion, osteophytes, and narrowing at the level of the craniovertebral junction have been reported..[3,20,22,36,44,48] Nagib and colleagues found patients with KFA with two unsegmented blocks of bone, cervical stenosis, or cranial involvement to be at highest risk for neurologic disturbances.[45-47] Those with only one unsegmented bone were found to be at low risk for cervical injuries. The flared trapezius muscles associated with KFA give the individual an appearance that may be similar to that seen in patients with Turner or Noonan syndrome.[8,13,18,38] The cervical vertebral anomalies and other defects of the spine that occur within the oculo–auriculo–vertebral spectrum may also be confused with those of KFA.[4,7,8,25,32,33,35,49,52,54,56]

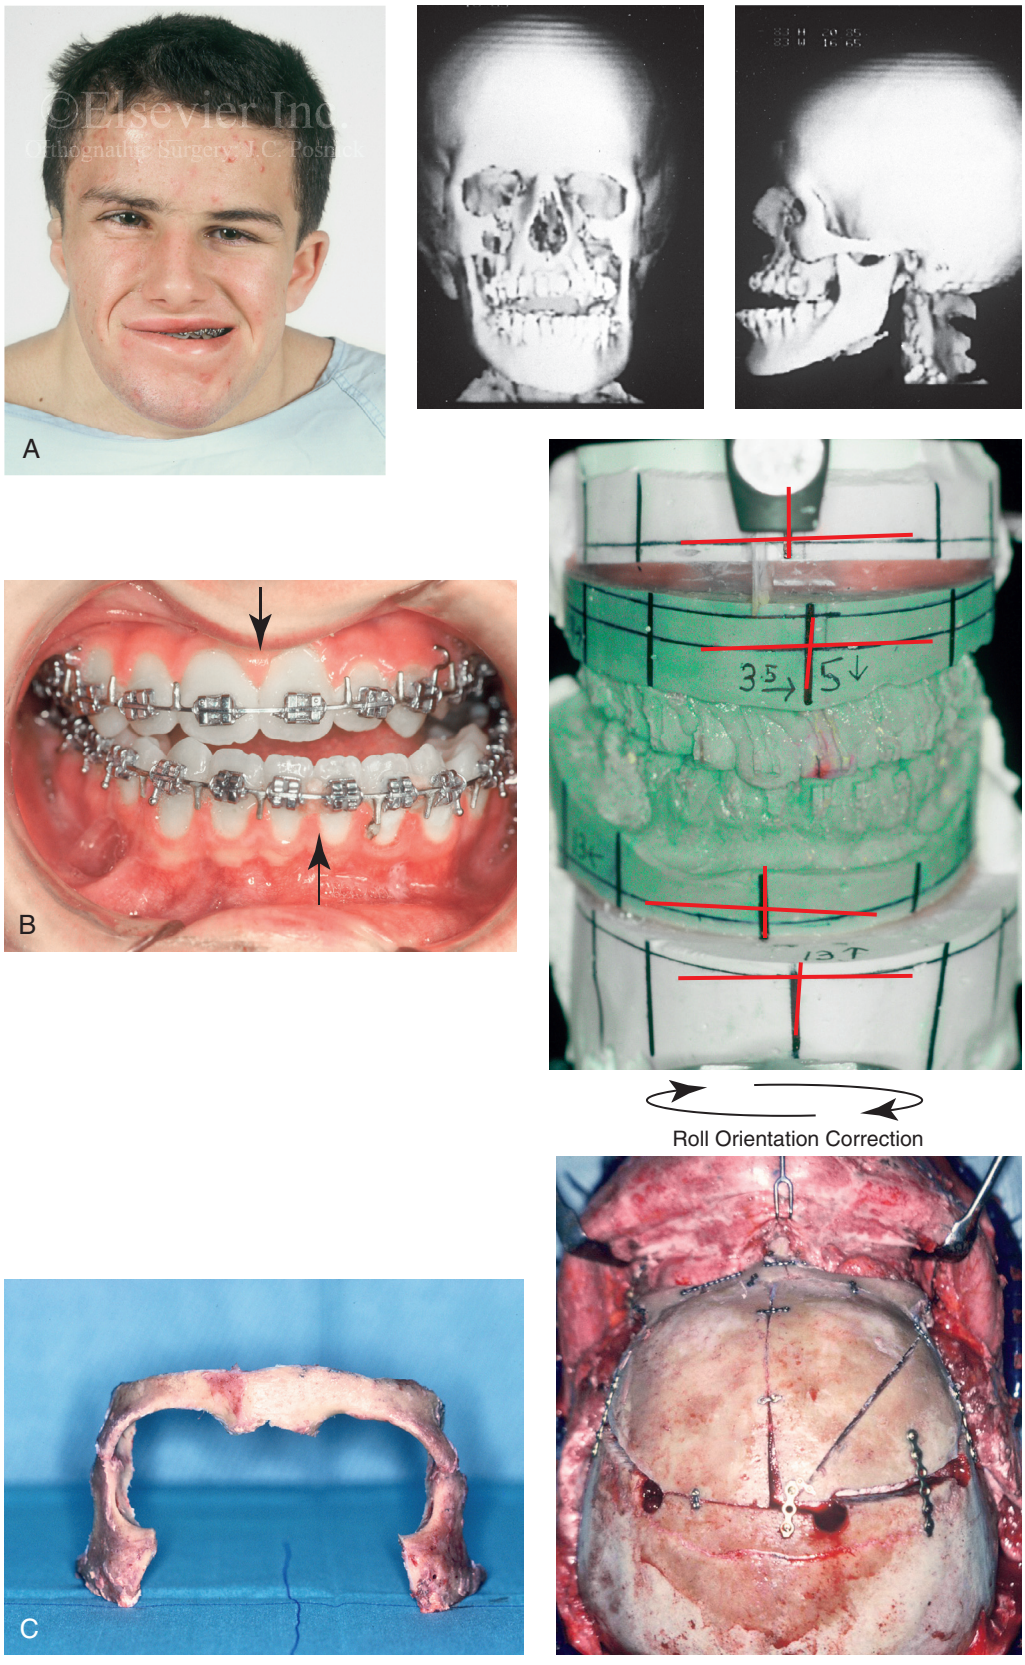
Author's Approach to Facial Reconstruction in Patients with Klippel–Feil Anomaly

The surgical management of KFA requires the accurate diagnosis of each specific problem (see Fig. 1-2).[17,26,31] Middle-ear infections should be treated promptly, and any hearing deficit should be aided whenever possible. Clefting of the secondary palate should be repaired in the usual way. Hypernasality as a result of inadequate soft palate motion after initial palate repair should be recognized and treated with a pharyngoplasty. Extraocular muscle abnormalities are managed with eye patching, spectacles, and eye-muscle surgery, as appropriate. The recognition of cardiovascular and genitourinary malformations should lead to medical treatment and surgery. Cervical spine instability requires the decompression of any nerve impingement and the fusion of unstable segments. Unfortunately, the typical fixed neck curvature observed in patients with KFA cannot safely be straightened.

The aim of the reconstructive procedures used to correct a webbed neck is to create as normal a neck contour as possible with a symmetrical posterior hairline while avoiding obvious scarring.[1] It is important to recognize that not all patients with webbed necks present with the same deformity. The clinician must assess the quality and quantity of available neck skin as well as the height and straightness of the cervical spine. Type I KFA consists of an extremely short skeletal neck that results in the increased width of the neck soft tissues. A spectrum of neck soft-tissue rearrangement procedures has been suggested to improve the webbed-neck deformity. Menick and colleagues modified the "butterfly" excision of redundant skin to avoid a midline scar.[41] They did this by extending the more traditional inferior flaps into the scalp. Unfortunately, with this design, the scars are displaced laterally, and they become visible at the hairline, close to the original site of the web. Some surgeons feel that a midline posterior scar is often preferred aesthetically to one that can be seen along the lateral neck region. The placement of tissue expanders followed by flap rearrangements has also been carried out with some success. Thus, to review, procedures designed to correct the webbed neck suffer from an inability to elevate the hairline, noticeable scarring, and the intrinsically inadequate height of the skeletal structures of the neck.

The craniofacial skeletal deformities of patients with KFA typically present in one of two patterns.[19,30,53] The first is in association with a congenital asymmetrical cervical spine fusion. In these patients, a variable degree of nonsynostotic anterior plagiocephaly is present. The ipsilateral fronto–orbito–zygomatic flattening and retrusion may be significant enough that anterior cranial vault, orbital, and zygomatic reconstruction carried out through an intracranial approach will be indicated to adequately improve morphology (Fig. 31-1). These individuals will also have an asymmetrical dentofacial deformity that requires Le Fort I (maxillary) osteotomy, bilateral sagittal split ramus osteotomies of the mandible, and an osseous genioplasty procedure for three-dimensional repositioning (Fig. 31-2). The most unsettling aspect of the craniofacial reconstruction relates to the fact that the neck cannot be straightened. It will remain crooked, and so decisions about the best aesthetic positioning of the osteotomized craniofacial skeletal units must also be adjusted.

The second pattern of presentation is in association with a congenital symmetric cervical spine fusion. The cranio–orbito–zygomatic region is symmetrical and has



• **Figure 31-1** A 17-year-old boy with Klippel–Feil anomaly has a fixed head tilt as a result of a painless cervical spine fusion and a partial facial nerve palsy on the right side. There is marked asymmetry and deformity of the craniofacial region that involves the upper facial skeleton (i.e., the cranial vault, the orbits, and the zygomas) and the lower facial skeleton (i.e., the maxilla, the mandible, and the chin). The reconstruction was compromised by the fixed head tilt and the CN VII deficit. The patient underwent cranio–orbito–zygomatic (intracranial) reconstruction through a coronal scalp incision followed by orthognathic surgery that included a Le Fort I osteotomy, bilateral sagittal split ramus osteotomies, and an osseous genioplasty. **A,** Frontal facial and computed tomography scan views before surgery. **B,** Occlusal view before surgery and articulated dental cast that indicates analytic model planning. **C,** Intraoperative view of removed orbital and zygomatic units and intraoperative bird's-eye view of the anterior cranial vault after cranio–orbito–zygomatic reconstruction.

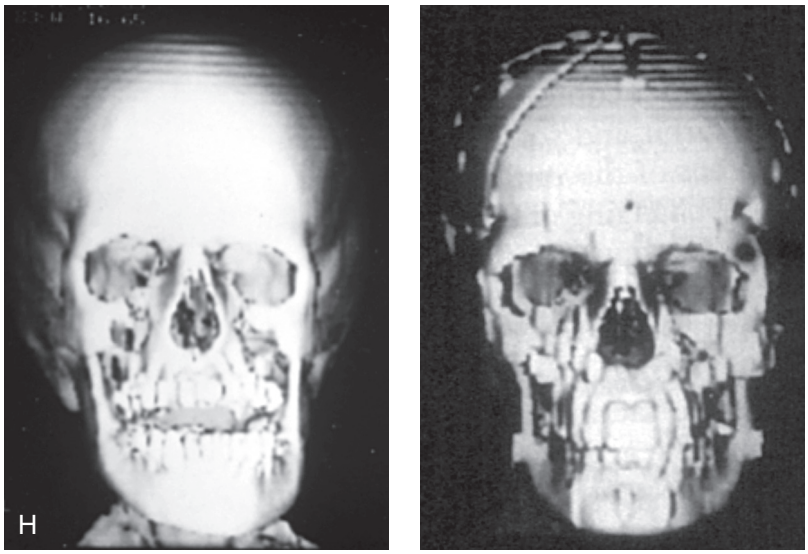
Orthodontics in progress with maxillary bicuspid extractions

After treatment



• **Figure 31-1, cont'd G,** Occlusal views with orthodontics in progress (including upper bicuspid extractions) and then after reconstruction. **H,** Three-dimensional computed tomography scan views before and after reconstruction.

relatively good proportions.[53] No reconstruction procedures are generally required in the upper facial skeleton. With reference to the maxillomandibular region, the constant open mouth posture of the mandible generally results in vertical maxillary excess and a constricted maxillary arch width. The mandible is usually retrognathic, with a vertically long retrusive chin and an open-bite malocclusion. A degree of maxillomandibular asymmetry is expected. The neck–chin angle is markedly obtuse. These individuals will benefit from orthognathic surgery in combination with orthodontic treatment. The orthognathic surgery will generally require a Le Fort I osteotomy in segments to intrude the maxilla vertically, advance it horizontally, and widen it transversely. The preferred approach also involves bilateral sagittal split ramus osteotomies of the mandible with horizontal advancement and counterclockwise rotation to match the new maxillary position in combination with a vertical reduction and advancement genioplasty (see Chapter 15).

Down Syndrome (Trisomy 21 Syndrome)

Background

Speculation about the historic prevalence of Down syndrome has included references to depictions of the syndrome in 15th- and 16th-century paintings.[69,81]

• **Figure 31-2** A teenage girl with the Klippel–Feil and Poland congenital anomalies has a fixed head tilt as a result of a painless cervical spine fusion. At birth, she was noted to have a significant diaphragmatic herniation of the stomach and spleen into the thoracic cavity. She underwent procedures for the correction of the diaphragmatic hernia and then required esophageal dilatations. She also required decompression and fusion for the cervical anomalies to limit injury to the upper spinal cord. She was referred to this surgeon as a teenager and underwent evaluations that included restorative dentistry, orthodontics, speech pathology, otolaryngology, pediatric surgery, pediatric orthopedic spine surgery, and pediatrics professionals. The assessment of pulmonary capacity, swallowing and dysphagia, and safe range of motion of the neck were of particular importance. There was marked asymmetry and deformity of the maxillomandibular region. The plans for reconstruction were affected by the fixed head tilt. The patient underwent a combined orthodontic and surgical approach, and her procedures included: maxillary Le Fort I osteotomy (horizontal advancement and cant correction); sagittal split ramus osteotomies (horizontal advancement and asymmetry improvement); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty and inferior turbinate reduction. Intraoperative cervical monitoring was carried out to limit the chance of spinal cord injury. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

Martínez-Frías described what seems to be the earliest observation of the syndrome in a sculpted terracotta head from 580 A.D.[89] The terracotta piece comes from the Toltec culture of Mexico, and its facial features, which include macroglossia, help to define its subject as a person with Down syndrome. The features of this Down syndrome were initially described by Langdon Down in 1866, and the condition represents a combination of phenotypic features that includes a degree of mental deficiency and characteristic facial features.[72]

The birth prevalence of trisomy 21 syndrome is generally stated to be 1 in 650 live births, but it is known to vary in different populations from 1 in 600 to 1 in 2000 live births. During the 1970s, 15% of patients who had been institutionalized for mental deficiency were found to have trisomy 21 syndrome.[75]

About 95% of all cases of Down syndrome arise from non-disjunction. Approximately 80% are of maternal origin, with 20% being of paternal origin. The risk increases with increasing maternal age as well as with paternal age and particularly when the parents are more than 35 years old. It has been estimated that approximately 4.8% of Down syndrome cases arise from an unbalanced translocation, which may occur de novo or by parental transmission. Inherited D/G translocations occur in 93% of maternal cases and 7% of paternal cases; however, for G/G translocations, 50% are of maternal origin, and 50% are of paternal origin. It has been estimated that 65% to 80% of trisomy 21 conceptuses result in spontaneous abortions.[75]

Detectable mosaicism (found in about 3% of trisomy 21 cases) and the Down syndrome phenotype may only be partially expressed.[75] The use of the DNA samples from individuals who have partial trisomy 21 with or without features of the phenotype has been helpful for understanding the nature of the disorder. The area between loci D21S58 and D21S42 has been identified as being associated with mental retardation and with most of the facial features of Down syndrome. The facial features that have been identified in this region include oblique palpebral fissures; epicanthal folds; a flat nasal bridge; a protruding tongue; short, broad hands with clinodactyly of the fifth finger; a gap between first and second toes; hypotonia; short stature; Brushfield spots; and characteristic dermatoglyphic findings, including a single palmar crease and an increased number of ulnar loops.[88]

Individuals with Down syndrome have a specific set of major congenital malformations, including heart anomalies (30% to 40%) and gastrointestinal tract anomalies such as duodenal stenosis or atresia, imperforate anus, and Hirschsprung disease.[75] The development of Alzheimer disease occurs at a much earlier age in individuals with trisomy 21 than it does in the general population. The frequency of symptomatic gallbladder disease is 25% higher among adults with Down syndrome as compared with the general population.

Down syndrome is characterized by extensive phenotypic variability.[65,67,71,98] Although cognitive impairment, muscle hypotonia at birth, and dysmorphic features occur to some extent in all individuals, most associated traits occur in only a fraction of affected individuals. In the patient with Down syndrome, a number of characteristic facial features that vary from patient to patient are frequently recognized:

1. Epicanthal folds
2. Oblique (anti-mongoloid) slanting of the eyelids
3. Strabismus as a result of extraocular muscle dysfunction
4. Flatness of the dorsum of the nose
5. Hypoplasia of the upper jaw that results in an Angle Class III malocclusion
6. Macroglossia
7. Microgenia

In 1967, Otermin Aguirre presented a series of patients with Down syndrome who underwent reconstructive surgery in an attempt to normalize their facial morphology.[93] During the same year, Hohler attempted to normalize the face of a young girl with Down syndrome by augmenting the hypoplastic dorsum of the nose and the receding chin with alloplastic implants.[77] In 1977, Lemperle and Spitalny systematically tried to normalize the faces of children with Down syndrome.[82-85] Similar results were published by Olbrisch,[91,92] Patterson and colleagues,[94] Wexler and Peled,[103,104] and Rozner,[99] in addition to several others.[76,90,94,97]

Despite the initial enthusiasm for facial reconstruction in children with Down syndrome during the late 1960s through the mid 1980s, a critical review of the procedures used to normalize the face was not carried out until the mid to late 1980s. In 1989, Katz and Kravetz presented a balanced, thoughtful review and a discussion of the literature regarding the "effectiveness of facial surgery for persons with Down syndrome."[79] The research of Katz and Kravetz may be summarized as follows: If improved functioning, appearance, and social acceptability are measured by parent and treating physician satisfaction, then the outcome of facial plastic surgery for people with Down syndrome seems positive. If function, appearance, and social acceptability are evaluated by people who were not involved in making the decision to conduct the facial plastic surgery—and particularly when control subjects are included in the evaluation—then the outcome of facial plastic surgery for people with Down syndrome is not so positive. For most patients with Down syndrome, the surgeons' and parents' well-intentioned attempts to normalize the child's facial morphology could not be realized.[96]

Macroglossia with protrusion of the large tongue is a frequent feature of Down syndrome. Dystonia or hypotonia of the tongue is also a factor.[66,74] During the 1970s and the early 1980s, several investigators suggested that partial glossectomy in the patient with Down syndrome could improve the clarity of speech.[68,70] However, studies that used objective criteria to document speech results after partial

glossectomy in patients with Down syndrome showed no significant differences in the number of articulation errors between audiotape recordings made preoperatively and 6 months postoperatively in a series of patients or between the recordings of the same patients and recordings of an additional series of Down syndrome control patients who did not undergo surgery. A further study by Margar-Bacal and colleagues looked at changes in the aesthetic appearance and intelligibility of speech after partial glossectomy in patients with Down syndrome.[87] The aesthetic appearance of speech (i.e., the visual acceptability of the patient while he or she is speaking) was judged from visual information only. Judgments of speech intelligibility were made separately from the auditory portion of the videotapes. The acceptability and intelligibility of the children were also judged together during audiovisual presentation. Statistical analysis showed that speech was significantly more acceptable aesthetically after surgery. No significant difference was found in speech intelligibility postoperatively as compared with preoperatively.

An Angle Class III malocclusion as a result of the midface hypoplasia with overclosure of the mandible is a frequent finding in patients with Down syndrome.[95] This was objectively studied by Farkas with the use of anthropometric measurements in which he documented that 60% of children with Down syndrome showed a disproportionately small depth to the middle third of the face (i.e., the anthropometric measurement from the subnasal point to the tragus).[73] The congenital absence of permanent teeth, poor root formation, and hypoplasia of the enamel are frequent complicating factors.

Author's Approach to Facial Reconstruction in Individual's with Down Syndrome

By the time that a individual with Down syndrome is 5 years old (with a formal speech and language assessment if the tongue is confirmed to be excessive in volume and if he or she is unable to comfortably maintain the tongue in the oral cavity), a conservative partial glossectomy may be useful to limit secondary skeletal deformities, improve breathing, and improve the aesthetic appearance of the child while he or she is eating or speaking and when his or her lower jaw is at rest. The basic procedure is a closing anterior wedge resection of the tongue that is carried out with the patient under general anesthesia. A variety of other techniques have also been described to conservatively reduce the size of the tongue.

When a child with Down syndrome approaches skeletal maturity (i.e., 14 to 16 years of age for girls, 16 to 18 years of age for boys) and a significant jaw deformity with malocclusion is present, then a comprehensive approach of orthodontic treatment and orthognathic surgery can effectively alter the facial proportions (aesthetics) and improve head and neck functions (i.e., lip posture, chewing, speech articulation, and breathing) (Fig. 31-3). A formal sleep study is indicated before surgery to clarify the extent of upper airway obstruction and the degree of maxillomandibular advancement required to manage it.[1,78,80,86,100-102] The orthodontic treatment may be compromised as a result of poor dental root formation, congenitally missing teeth, or limited compliance. The coordination of care with an appropriate dental team (e.g., a restorative dentist, a periodontist, an orthodontist) is useful before the initiation of any treatment.

The correction of the dentofacial deformity and the management of the airway frequently requires maxillary Le Fort I osteotomy (horizontal advancement and vertical lengthening), often with sagittal split ramus osteotomies for alignment to the new maxillary position (i.e., advancement but not setback) and an osseous genioplasty (horizontal advancement and vertical lengthening). Septoplasty and inferior turbinate reduction should be simultaneously performed if required to improve nasal airflow (see Chapter 10).

Unfortunately, the numerous adnexal (eyelid) soft-tissue procedures described in the literature (e.g., lateral canthopexy) in an attempt to normalize the faces of patients with Down syndrome have mostly proven to be suboptimal.

Neurofibromatosis

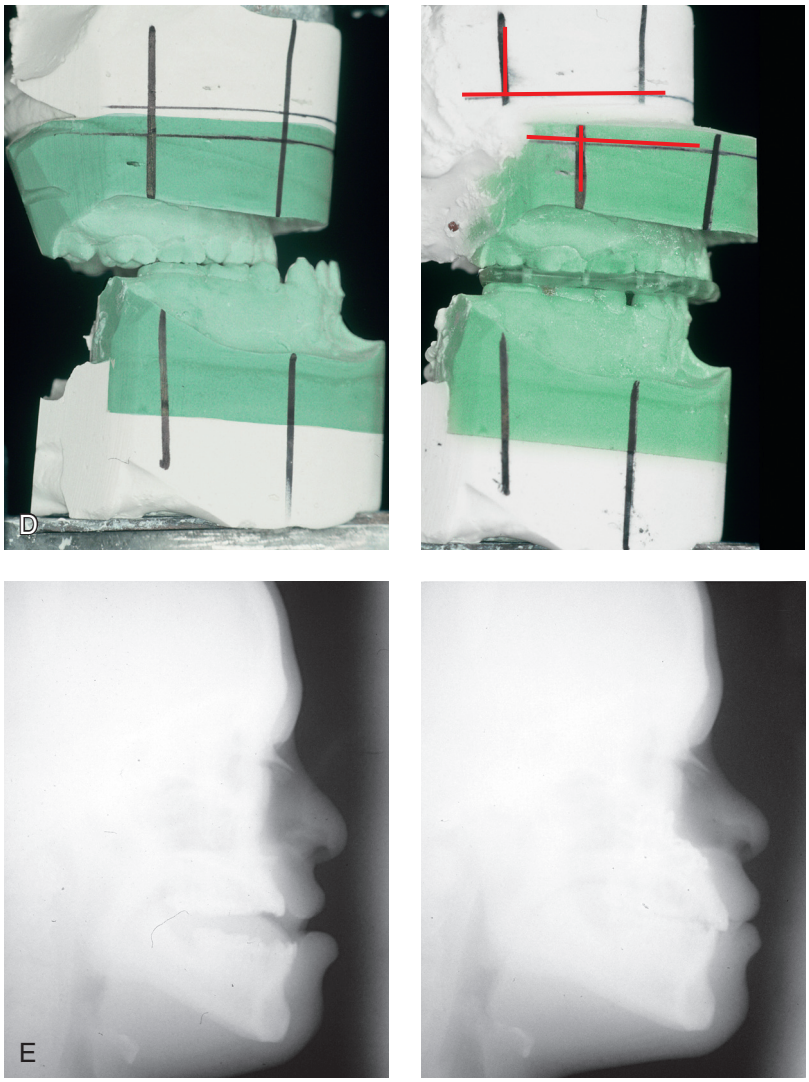
Background

In 1849, Robert Smith, a professor of surgery at Dublin Medical School, reported clinical and necropsy findings in two cases of individuals who were presumed to have neurofibromatosis; he cited 75 references to similar patients from the earlier medical literature.[130] Unfortunately, he did not recognize that the tumors (neurofibromas) contained neural elements. In 1882, von Recklinghausen published his findings, which convinced the medical world that neurofibromatosis was a distinct entity of neural origin.[165] Today, neurofibromatosis is known to be etiologically heterogeneous. Cohen and Hayden were the first to differentiate Proteus syndrome from neurofibromatosis in 1979.[119,162] Types I and II are the forms that are frequently encountered by the craniomaxillofacial surgeon.

Neurofibromatosis Type II (Acoustic Type)

The hallmark of Type II neurofibromatosis is the presence of bilateral acoustic neuromas.[147,150] Symptoms are usually caused by pressure on the vestibulocochlear and facial nerve complex. The first symptom is usually hearing loss that often begins during the teenage years or the early 20s. Occasionally, hearing loss may occur as early as the first decade or as late as the seventh decade of life. Cafe-au-lait spots and cutaneous neurofibromas are also present, but they are seen less frequently than they are among patients with neurofibromatosis Type I.[121] Tumors of the central nervous system are especially common, with Schwann cell tumors occurring most frequently. Multiple tumors of meningeal or glial origin may also occur.[147] Neurofibromatosis Type II has autosomal dominant inheritance with penetrance of more than 95%. The responsible gene has been mapped to chromosome 22.

• **Figure 31-3** A 16-year-old boy with Down syndrome presented with a jaw deformity and malocclusion. He underwent a combined orthodontic and surgical approach. The surgery was limited to a Le Fort I osteotomy (horizontal advancement and vertical lengthening). **A,** Frontal views before and after reconstruction. **B,** Profile views before and after reconstruction. **C,** Occlusal views before and after reconstruction. Note that the orthodontic and restorative dental objectives were limited by congenital malformations of the dental crowns and dental roots.



• **Figure 31-3, cont'd D,** Articulated dental casts that indicate analytic model planning. **E,** Lateral cephalometric radiographs before and after reconstruction.

Neurofibromatosis Type I (von Recklinghausen Type)

Joseph Merrick, the Elephant Man, has often been thought to have had von Recklinghausen disease. However, after considering several diagnostic possibilities, Cohen concluded that Merrick's skeletal findings are most consistent with Proteus syndrome.[119,130,162]

This classic form of neurofibromatosis accounts for approximately 90% of all affected cases. Major features include six or more cafe-au-lait spots, cutaneous neurofibromas, and Lisch nodules.[130] Axillary freckling develops in about 66% of all patients. Neurofibromatosis type I, which is the classic form of neurofibromatosis, is the one described by von Recklinghausen; it is also the most frequent form, occurring in 1 of every 2500 to 3000 births.[146,160,165,166] Inheritance is autosomal dominant, with almost 100% penetrance. Approximately 50% of cases represent new mutations, and an increase in paternal age at the time of conception has been found to be an associated feature. Although most evidence points to neurofibromatosis as a disorder of neural crest derivation, some controversy remains about whether the neural and mesenchymal components are interrelated or if they may arise independent of each other.[110,116,153]

Type I is caused by a mutation of the neurofibromin 1 (NF1) gene. Approximately 5% to 20% of all patients with Type I neurofibromatosis patients carry a heterozygous deletion of approximately 1.5 Mb that involves the NF1 gene and the contiguous change line in its flanking region.[157] Miller and Hall found that patients born to affected mothers have more severe disease than those born to affected fathers.[152] The mutation rate in the NF1 gene is one of the highest known in humans, with approximately 50% of all patients with NF1 presenting with novel mutations.[124]

The natural history of neurofibromatosis Type I has been reviewed by several authors.[138] More than 40% of patients have some clinical manifestations at birth, and more than 60% have manifestations by the second year of life. Cafe-au-lait spots usually develop first, with multiple lesions

present within the first year of life. In approximately 50% of patients, axillary freckling appears later. Cutaneous neurofibromas appear around the onset of puberty and increase in number throughout life.[138] Lisch nodules begin to appear during early childhood and have been observed in almost all affected adults. Plexiform neurofibromas occur in 30% of these patients.

Approximately 33% of all patients develop one or more complications in association with the disease.[105-108,115] It has been estimated that some form of malignancy develops in 6% of patients with neurofibromatosis type I who are more than 18 years old.[109,117,118] Other important complications that may occur are neurologic and include epilepsy, aqueduct stenosis, and spinal neurofibromas. Learning disabilities of various kinds affect 25% of patients.[137,154,163]

Any part of the eye may be involved.[111,126,128,132] Lisch nodules of various sizes may be found anywhere in the iris. These lesions are melanocytic hamartomas, and they are found only in patients with neurofibromatosis. Phakoma, congenital glaucoma, corneal opacity, detached retina, optic atrophy, and congenital ptosis of the eyelids have all been reported. Intraorbital lesions may also produce proptosis and eye-muscle palsies.

The literature concerning the presenting head and neck dysmorphology and the suggested treatment of orbitotemporal neurofibromatosis is extensive.* The plexiform neurofibroma that involves the orbit, the eyelid, and the temporal region may also have an intracranial component. It generally appears during childhood as a swelling of the upper eyelid, and it slowly and progressively worsens (Fig. 31-4). Further involvement of the subcutaneous tissues of the eyelids with varying degrees of ptosis and proptosis of the globe also occurs. For patients in whom progression continues, there is further plexiform neurofibromatosis of the temporal area, pulsating proptosis, continued enlargement of the eyelids with extensive mechanical ptosis, and the inability to open the eye, which results in severely diminished visual acuity or blindness. The globe itself is involved with neurofibroma, and buphthalmos may be present. The eye may be painful as a result of infection and epiphora.

The primary skeletal abnormalities associated with type I neurofibromatosis include long bone dysplasia, sphenoid wing dysplasia, and scoliosis. The unilateral nature of the skeletal involvement suggests a random molecular event. The classic upper face skeletal malformations and deformities include an absence of the greater wing of the sphenoid that may be either partial or complete. As part of the sphenoid wing malformation, there may be a defect of the posterolateral orbital wall and enlargement of the superior orbital fissure with prolapse of the temporal lobe of the brain into the orbit and the temporal fossa region. This further pushes the globe anteriorly and inferiorly, and it may cause pulsatile exophthalmos. The intraorbital volume may be greatly enlarged, and the orbit may be abnormally shaped. The lateral and infraorbital rims are displaced outwardly and inferiorly in addition to being thinned. The orbital floor is depressed, and the orbital roof and the supraorbital rim are elevated. The zygoma is often dysplastic and inferiorly displaced.

Author's Approach to Reconstruction in Patients with Orbitotemporal Neurofibromatosis

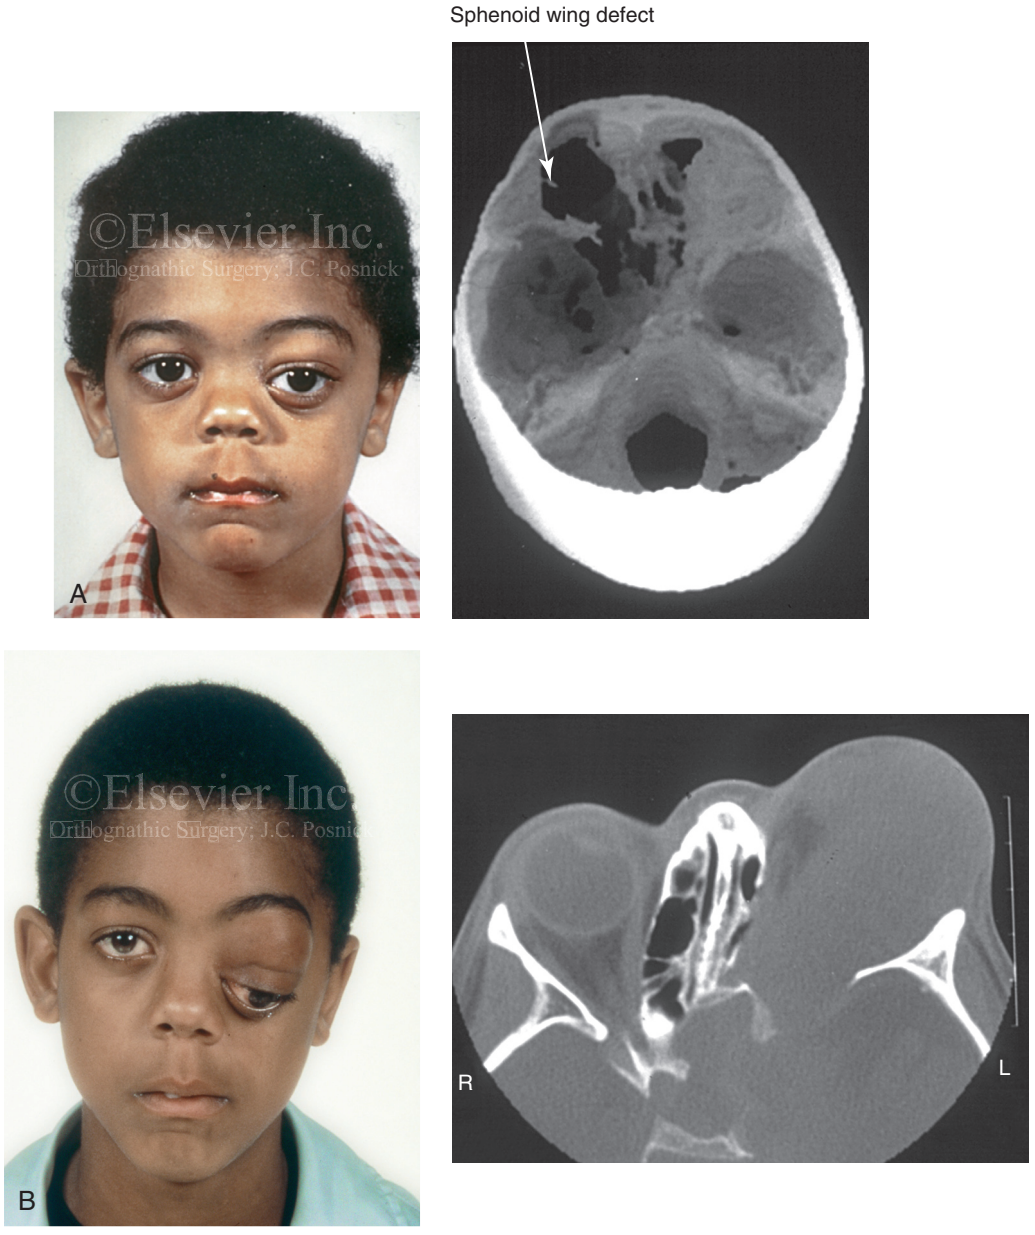
It is recognized that the facial reconstruction of patients with this condition is often difficult as a result of the multilevel involvement of the skeleton, the soft tissues, and the viscera (i.e., brain, eyes, tongue, soft palate, sinus, and teeth). A basic premise of treatment is to preserve the seeing eye whenever feasible.[114,127,135,136,155,158,159,161] The prevention of brain injury and the improvement of the tongue, lips, soft palate, and jaw function are high priorities. Jackson and colleagues have suggested a classification system for orbitotemporal neurofibromatosis that they have found useful for treatment planning[139]:

1. Orbital soft-tissue involvement with a seeing eye
2. Orbital soft-tissue and significant bony involvement with a seeing eye
3. Orbital soft-tissue and significant bony involvement with a blind or absent eye

It has been pointed out by Jackson and others that conservative surgical debulking procedures that leave considerable amounts of the plexiform neurofibroma leave patients prone to continued growth and the need for further surgery.[141] Whenever feasible, more complete resection of the tumor with immediate reconstruction is preferred.

When the temporal–cheek region is extensively involved, the facial nerve presents an extra challenge. If possible, the facial nerve is dissected free, the tumor is debulked, and the soft-tissue flaps are redraped (see Fig. 31-4). When the facial nerve is extensively infiltrated by a tumor that grotesquely deforms the face, it may be necessary or preferable to resect the nerve as part of the debulking procedure. Occasionally we have used an approach that involves the radical debulking of the tumor, the planned sacrifice of the involved facial nerve, and the simultaneous reconstruction of the cheek–facial nerve defect with a reinnervated free muscle transfer.

Despite the less than ideal restoration of function and enhancement of facial aesthetics that is often achieved with the presenting orbitotemporal, temporal–cheek, and maxillomandibular neurofibromatosis deformities, patients and families are generally pleased with the efforts (see Fig. 31-4). Longitudinal computed tomography scanning and magnetic resonance imaging reassessment are useful to follow the disease process, because residual neurofibromatosis generally remains, and malignant transformation may occur.



• **Figure 31-4** A child with neurofibromatosis involving the left cranio–orbital region. Aplasia of the sphenoid wing and the gradual growth of plexiform neurofibroma occurred, which extended from the cavernous sinus through the widened superior orbital fissure, through the cone of the eye, and into the upper eyelid. Despite an intracranial debulking procedure carried out by another surgeon during the patient's middle childhood years, the boy presented to this surgeon with residual and recurrent plexiform neurofibroma that resulted in the distortion and proptosis of the left eye. Vision remained in the affected eye, and the decision was made to preserve it. The patient underwent intracranial reconstruction of the cranio–orbito–zygomatic skeleton, including the debulking of the soft-tissue tumor and the vertical and horizontal debulking of the upper eyelid. Intracranial debulking with eye presentation was accomplished. **A,** Frontal view during early childhood and a computed tomography scan of the anterior skull base indicating the defect in the sphenoid wing. **B,** Frontal view at 10 years of age. Despite a debulking procedure carried out by another surgeon, residual growth has reoccurred. An axial computed tomography scan view through the midorbits indicates the extent of plexiform neurofibromatosis from the cavernous sinus through the upper eyelid.

Hemihyperplasia of the Face

Background

Hemihyperplasia was first described by Meckel in 1822.[192] Many comprehensive reviews have been published since that time.[173,174,181,182] In patients with hemihyperplasia, the enlarged area may run the gamut from a single digit to a single limb to unilateral facial enlargement to involvement of half of the body.[168-170,179,183,187,189,198,199,203,206-208] In some patients, the defect is limited to a single tissue type (e.g., muscular, vascular, skeletal, nervous system).[204]

The etiology and pathogenesis of hemihyperplasia are poorly understood, with a variable range of clinical abnormalities having been described.[171,175,178] This fact—in combination with the large number of reported sporadic cases—is suggestive of etiologic heterogeneity. When the face is involved, asymmetry is usually evident at birth, and it may become accentuated or at least more of a concern with age, especially at puberty.[180,188,190,192,196,200-202] The involved bones have been found to be unilaterally enlarged, often with accelerated bone age on the affected side. A variety of non-neoplastic abnormalities of the limbs, teeth, skin, central nervous system, cardiovascular system, liver, kidneys, and genitalia have also been observed.

Various neoplasms have been reported in association with hemihyperplasia, including Wilms tumor, adrenal cortical carcinoma, and hepatoblastoma to name but a few.[172,176,177,184-186,191] In the study by Hoyme and colleagues of 104 cases of isolated hemihyperplasia, tumors developed

in 3.8% of patients.[186] The neoplasms associated with hemihyperplasia have been found to have an embryonal origin. Patients with hemihyperplasia should be screened with ultrasound for tumors every 6 months for the first 4 years of life and probably less frequently thereafter until the age of 7 years.[176,184]

Any and all ipsilateral facial structures may be involved, including the bones of the cranium, the orbit, the zygoma, the maxilla, and the mandible.[193-195] Premature development and eruption of the teeth occur, as does macrodontia of varying degrees. Unilateral enlargement of the tongue and its papillae is also a frequently observed feature. The overall facial soft tissues are increased in thickness, size, and volume. The eyeball and even the brain may be enlarged on the affected side.

Hemihyperplasia of the face should be distinguished from hemimandibular hyperplasia (HMH), which is a three-dimensional enlargement of the whole hemimandible but not of the other facial structures.[193-195] Furthermore, in patients with HMH, no other aspects of the body are enlarged, and no predisposition to tumors has been identified. HMH was first reported by Adams in 1836.[182] Epidemiologic data suggest that there is equal incidence of HMH in both sexes and in all ethnic groups. Obwegeser drew the distinction between HMH and hemimandibular elongation.[193-195] He also clearly differentiated these conditions from hemihyperplasia of the face (see Chapter 22).

Author's Approach to Reconstruction in Patients with Hemihyperplasia

Procedures to improve facial symmetry and Euclidian proportions for the individual with hemihyperplasia of the face are offered when feasible (Fig. 31-5).[197] Overzealous attempts to debulk the soft-tissue enlargement (e.g., resection of the parotid gland, resection or liposuction of the deep layer soft tissues of the cheek) may result in damage to the facial nerve or introduce an "operated" look and are thus generally discouraged.[205] Surgery should be directed at regions and tissue layers that are most amenable to safe improvement. Orthodontic treatment in combination with orthognathic surgery is often a fruitful approach. A maxillary Le Fort I osteotomy to bring the maxillary dental midline back to the facial midline; to correct canting; and to adjust the vertical dimension, horizontal projection, and arch width is frequently useful. This is combined with bilateral sagittal split ramus osteotomies of the mandible to reposition the jaw and also to recontour the inferior border. An oblique osteotomy of the chin for repositioning and also to recontour the inferior border is carried out (see Fig. 31-5).

Vascular Malformations

Background

Vascular anomalies fall into two groups: hemangiomas and vascular malformations. Mulliken and Glowacki were the first to clarify a biologic classification of vascular anomalies on the basis of endothelial properties.[226,231,232] Those authors described how hemangiomas have a proliferative endothelium whereas vascular malformations have a stable endothelium.[218] Hemangiomas have a natural history that is characterized by initial proliferation, stability, and then at least partial involution (Figs. 31-6 and 31-7). Vascular malformations are present at birth, although they may not be clinically evident until sometime later during childhood. In general, vascular malformations grow commensurately with the child, but they may expand suddenly as a result of trauma, infection, or hormonal influences (Figs. 31-8 through 31-11). Vascular malformations generally occur sporadically, although inherited autosomal dominant entities do exist. The International Society for the Study of Vascular Anomalies classification system is based on Mulliken and Glowacki's work.[226] Vascular tumors include hemangiomas, Kaposiform hemangioendotheliomas, tufted angiomas, pyogenic granulomas, and hemangiopericytomas. Vascular malformations include capillary, venous, lymphatic, and arteriovenous conditions; malformations can also be mixed and include combinations of these. From a clinical perspective, it is useful to think in terms of the flow characteristics of the malformations (i.e., either slow flow or fast flow) and the type of vessel drainage.[213-215,217,223-228]

Complications from vascular malformations include venostasis, ischemia, coagulopathy, disseminated intravascular coagulopathy, heart failure, and even death.[209] Skeletal anomalies can occur as a result of intraosseous involvement, skeletal expansion, or skeletal compression (erosion). Any head and neck function can be affected by the presence of a vascular anomaly's tumor-like mass.

The diagnostic imaging of vascular malformations primarily relies on radiographic modalities.[212] Phleboliths are generally pathognomonic for venous malformations. Color Doppler ultrasound is an invaluable tool for the assessment of blood flow velocities and patterns of vascular lesions. Computed tomography plays an important role in the understanding of skeletal involvement. Magnetic resonance imaging is a useful non-invasive and non-ionizing test for the accurate depiction of soft-tissue relationships and allows slow-flow malformations to be accurately differentiated from high-flow malformations. Angiography and venography can play important diagnostic and therapeutic roles in the management of specific vascular malformations. Advantages of venography include the clarification of lesion size and extent and of venous drainage patterns. Angiography can clarify arteriovenous shunting, the presence of macrofistulae and microfistulae, and the location of the lesion's nidus. Therapeutic embolization via angiography with the use of particular materials or coils can be carried out.

Lymphatic Malformations

Lymphatic malformations are slow-flow anomalies.[223,225,226,228] Macrocystic lesions are easier to deal with than microcysts. Microcystic lesions do not resolve

• **Figure 31-5** A 16-year-old girl with left hemihyperplasia of the face that affects both the soft tissues and the skeletal structures. There were distortions of the maxilla and the mandible that were treated through a combined orthodontic and surgical approach. The patient underwent a Le Fort I osteotomy (vertical intrusion and improvement of canting and asymmetry), bilateral sagittal split ramus osteotomies (improvement of asymmetry), and an osseous genioplasty (vertical reduction and horizontal advancement). Note that improvements in the facial skeleton were possible but that the soft-tissue fullness remains. **A,** Frontal views before and after reconstruction. **B,** Profile views before and after reconstruction.

• **Figure 31-5, cont'd C,** Worm's-eye views before and after reconstruction confirm residual soft-tissue fullness. **D,** Occlusal views before and after reconstruction. Note: Maxillo-mandibular reconstruction does not address the soft tissue enlargement.

spontaneously, and they are often harder to manage surgically as a result of their close integration within the normal head and neck soft tissues that must be preserved. Only half of lymphatic lesions are recognized at birth, but the majority are evident by approximately 2 years of age. Skeletal and soft-tissue overgrowth are typical in the craniomaxillofacial region. Cervicofacial lymphatic malformations tend to present with skeletal distortions (e.g., mandibular overgrowth, malocclusion). There may be intraosseous involvement, but skeletal expansion and erosion (remodeling) as a result of mass effect are typical. Symptoms of localized swelling, pain, and erythema associated with infection are common. Significant complications include intralesional bleeding and infection that are often associated with rapid expansion and then moderate regression. Rapid swelling can lead to airway obstruction. Macrocysts may undergo involution if they are ruptured by trauma, or they may be treated via the injection of sclerosing agents or aspiration. However, surgical removal should be considered, when feasible. Complete resection is seldom possible because lymphatic malformations often surround and incorporate normal anatomy that is not deemed appropriate for resection (see Figs. 31-8 and 31-9).[220-222,229,230] Orthognathic procedures would frequently be beneficial but are not often carried out.

Venous Malformations

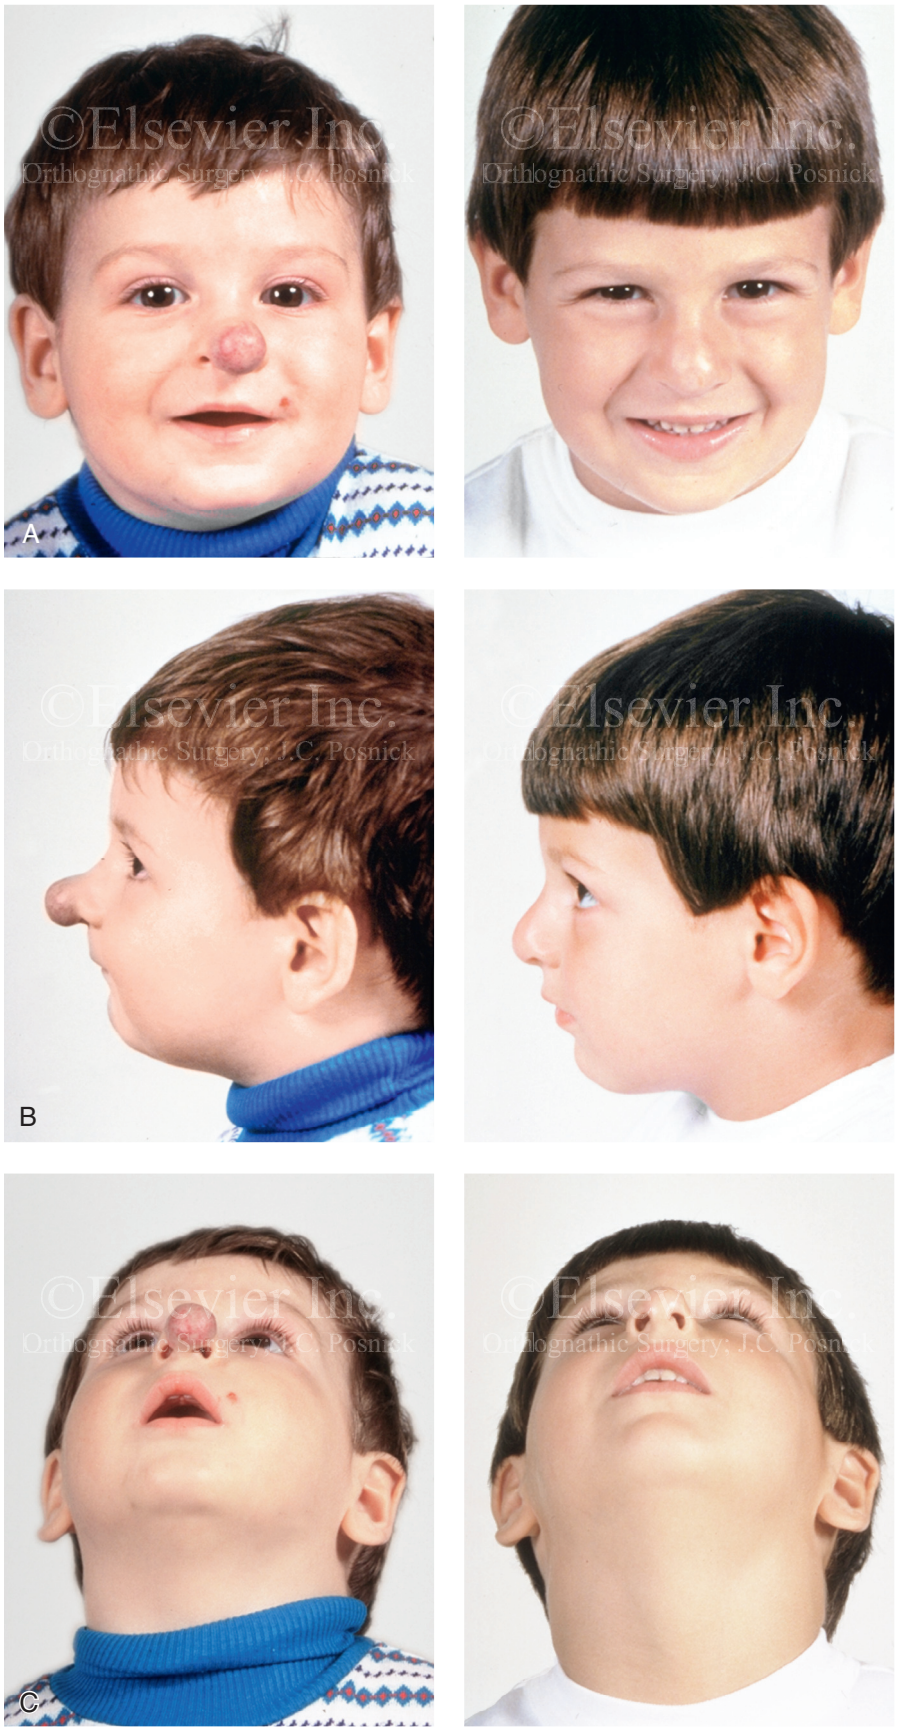
Venous malformations are the most common form seen in the head and neck region.[223,225,226,228] They are present at the time of birth, but they may not have been recognized, or they may have been misdiagnosed.[210,219] Histologically, they are composed of variably sized, thickened, dilated, spongy channels that are devoid of smooth muscle and lined by endothelial cells. Clinically, they are compressible subcutaneous masses that are often deep blue in color. They generally grow commensurate with the child but, as with lymphatic malformations, trauma, infection, and hormonal

• **Figure 31-6** A 5-year-old boy with a hemangioma that involves the soft tissues of the forehead and the upper nose (glabella region) is shown before and 2 years after undergoing a direct vertical midline excision. Note that the soft-tissue growth did not significantly resorb (compress) the underlying skeleton. **A,** Frontal views before and 4 years after reconstruction. **B,** Oblique views before and 4 years after reconstruction.

changes can cause rapid expansion. Venous malformations can involve any tissue layer (i.e., skin, mucosa, muscle, brain, bone, or viscera). Thrombosis within the malformation commonly leads to phlebolith formation. When present, phleboliths are pathognomonic and assist with the accurate diagnosis. Venous malformations are usually unilateral and result in significant facial asymmetry and dysfunction. They may affect speech, swallowing, chewing, breathing, vision, hearing, cognition, and jaw or neck range of motion. They may be intraosseous or have secondary effects on the bone (i.e., expansion, remodeling, or resorption). Treatment to reduce the size of venous malformations includes the injection of sclerosing agents in an attempt to damage the endothelial cells via intravascular thrombosis and fibrosis as well as partial surgical excision (see Figs. 31-8, 31-9, and 31-10).[220,221,222,229]

Arteriovenous Malformations

Arteriovenous malformations are high-flow malformations with a direct connection between an artery and a vein, with no intervening capillary bed.[223,225,226,228] These malformations are also present at birth, but they may have gone unrecognized or have been misdiagnosed as a more



• **Figure 31-7** A 5-year-old boy with a hemangioma that involves the soft tissues of the tip of the nose. He is shown before and after undergoing surgical debulking through a columella-splitting open rhinoplasty technique. The soft-tissue growth displaced but did not destroy the lower lateral cartilages (LLC) or septum; the LLC were reconstructed with the use of a suture pexy technique after tumor debulking. **A,** Frontal views before and after reconstruction. **B,** Profile views before and after reconstruction. **C,** Worm's-eye views before and after reconstruction.

• **Figure 31-8** A newborn child with a massive low-flow mixed (lymphatic–venous) vascular malformation that involved the right side of the face, neck, chest wall, upper arm, and upper back. The malformation was recognized through ultrasonic evaluation during fetal development, and the child was delivered by Cesarean section with a good airway. At 6 weeks of age, he underwent a planned single staged surgical debulking procedure. He retains good cranial nerve and brachial plexus function. Portions of the sternocleidomastoid, trapezius, and platysma muscles were sacrificed in the process. No significant deformation of the craniofacial skeleton resulted. **A,** Frontal facial views before surgery, at 7 months of age, and then at 5 years after resection. **B,** Posterior facial views before surgery, at 7 months of age, and then 5 years after resection. The patient is shown with both arms extended, which indicates satisfactory neuromotor control.

straightforward hemangioma. The confirmation of clinical diagnosis is helpful with color Doppler examination, which can determine flow rate, volume, and reversal of flow. Magnetic resonance imaging can determine the extent of the lesion and its relationship with the surrounding anatomy. Angiography can further clarify the lesion and be used for the therapeutic embolization of an arteriovenous malformations. If an arteriovenous malformation is well localized and can be reliably excised with satisfactory reconstruction, this is always a first choice (see Fig. 31-11). Unfortunately, larger, more extensive lesions are not surgically resectable. Superselective embolization performed by an experienced interventional radiologist with the placement of an ablative agent (e.g., absolute alcohol, sodium tetradecyl sulfate) to induce the destruction of the endothelium may be useful. Embolization that involves coils or particles is another technique for temporarily occluding flow. The ligation of feeding vessels or proximal embolization is generally avoided, because rapid collateralization tends to occur.[220,221,222,229]

Capillary Malformations

Capillary malformations, which were previously referred to as *port-wine stains,* are intradermal vascular anomalies.[223,225,226,228] They occur in less than 1% of newborns, and they have an equal distribution in male and female individuals.[216] They typically present as either pink or red cutaneous discolorations. They have a tendency to darken, thicken, and become nodular with age. Several conditions are associated with capillary malformations, including Sturge–Weber syndrome, which presents with capillary malformations in the trigeminal nerve distribution in combination with vascular anomalies of the leptomeninges,

often with a seizure disorder, developmental delay, and eye involvement (i.e., glaucoma and retinal detachment).[211] Proteus syndrome may also be associated with cutaneous vascular malformations.[215] When feasible, the treatment of capillary malformations with a pulsed dye laser should be considered.

Velocardiofacial Syndrome

Background

Velocardiofacial syndrome (VCFS) is a genetic condition that is characterized by abnormal pharyngeal arch development that results in defective development of the thymus, the parathyroid glands, and the conotruncal region of the heart. Shprintzen and colleagues first described this syndrome in1978.[249] Since then, almost 200 different individual clinical features have been associated with VCFS.[233,240,247] No single individual has been found to have all of the described features. Affected individuals will present with unique facial features, and they may also have cardiac defects, palatal abnormalities, hypernasal speech, hypotonia, defective thymic development, and a variety of learning disabilities.[248]

Approximately 75% of individuals with VCFS have cardiac anomalies. The cardiac defects are usually of the conotruncal type.[234,242] The most common variations include an interrupted aortic arch (50%), truncus arteriosus (35%), and tetralogy of Fallot (16%). Palatal abnormalities predispose these individuals to speech difficulties. Defective thymic development is associated with impaired immune function. Learning disabilities include overt developmental delay, psychiatric disorders, and musculoskeletal defects.[238] Interestingly, ophthalmologic abnormalities occur in approximately 70% of individuals with VCFS; these may include bilateral cataracts, tortuous retinal vessels, and small optic discs.

Approximately 10% of individuals with VCFS will have DiGeorge syndrome, which consists of at least two of the three following features[239]:

1. Thymic aplasia (immune deficiency)
2. Hypoparathyroidism (hypocalcemia)
3. Conotruncal cardiac anomalies

Approximately 15% to 20% of patients with VCFS will be born with Pierre Robin sequence (see Chapter 4). Many individuals are mistakenly categorized as having CHARGE syndrome.

Pathophysiology

VCFS is now known to be a congenital disorder that is caused by a microdeletion at the Q11.2 band, which is located on the long arm (Q) of chromosome 22.[235,243] The microdeletion is known to cause an abnormality of morphogenesis that affects the migration of the neural crest cells and therefore the early development of branchial arches. In approximately 90% of affected individuals, the disorder occurs as a result of a new mutation. In the other 10% of cases, the disorder is inherited from a parent in an autosomal dominant fashion. Affected individuals have a 50% chance of passing VCSF to each offspring.[244]

Epidemiology

The prevalence of VCFS is the United States is approximately 1 in 2000 live births. Internationally, the syndrome occurs in 1 in 4000 live births. The frequency of VCFS in newborns with isolated cleft palate is approximately 8%. There seems to be no gender predilection. The syndrome is present at birth, but it is often unrecognized until childhood or later.[237] Although the heart defect or the cleft palate is generally detected soon after birth, the learning disorders and psychiatric illnesses may not become apparent until the school-aged years.[236] Even then the correct diagnosis is not always made.

DiGeorge syndrome, which involves a total absence of the thymus and a severe T-cell immunodeficiency, is found in less than 0.5% of patients with VCFS.[236,241,245] Most affected individuals have only partial defects, with impaired thymic development and variable defects in their T-cell numbers.

Author's Approach to Reconstruction in Patients with Velocardiofacial Syndrome

Evaluation by clinicians who have experience with clefting usually centers around the issue of hypernasal speech and whether or not a palatal procedure is indicated. Concern about the location of the carotid arteries (when considering the use of a pharyngeal flap) is always part of the discussion.[246]

A percentage of teenagers with VCFS will present with a jaw deformity and malocclusion. These patients will benefit from a comprehensive orthodontic and surgical approach. They generally have a long face growth pattern (see Chapter 21) and require osteotomies of the maxilla, the mandible, and the chin region (Fig. 31-12).

Conclusions

Many hundreds of syndromes and anomalies produce a spectrum of head and neck dysfunction and facial disproportion within the maxillofacial region. Each syndrome type and its presenting set of anomalies will be unique, with individual variations that must considered.

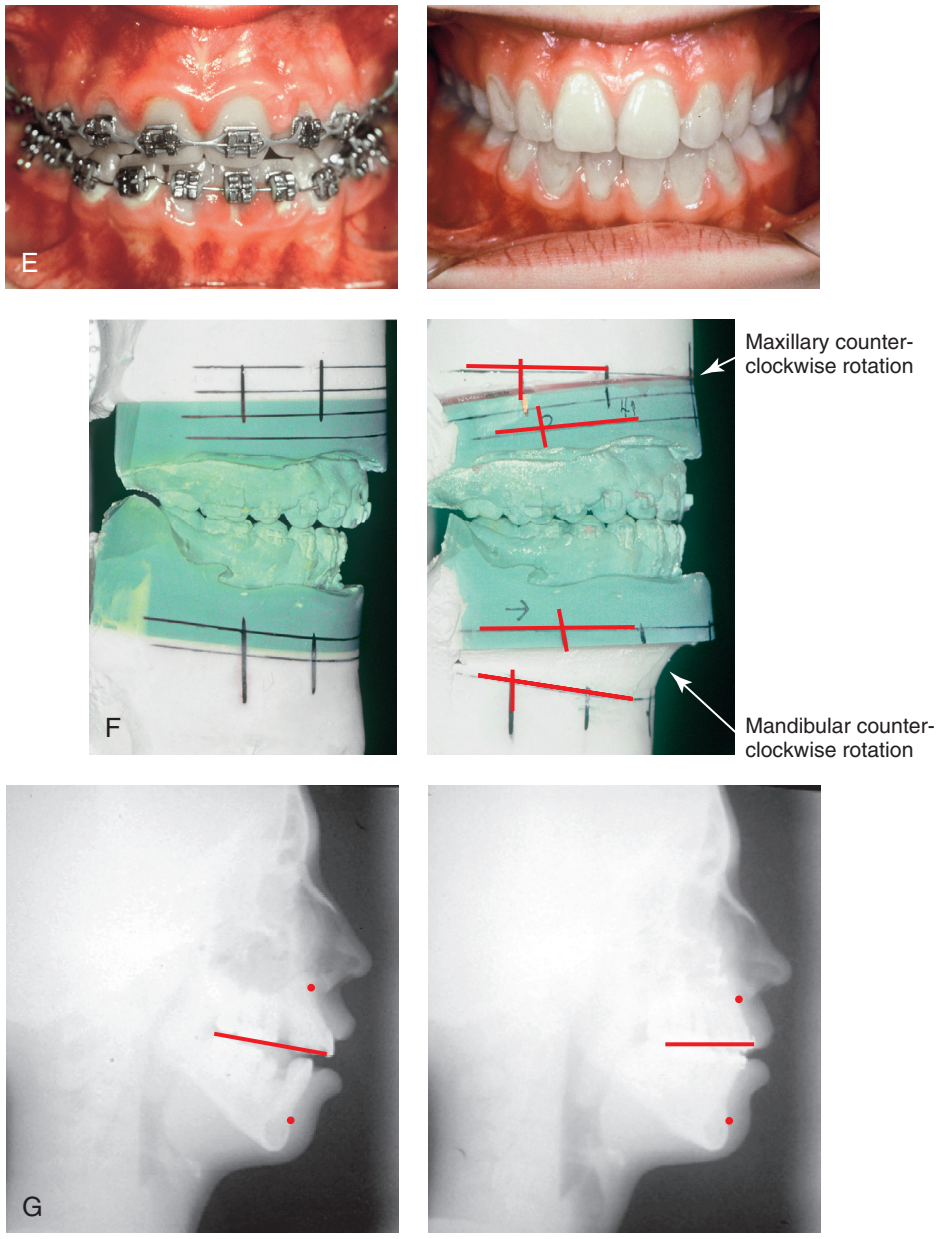
Orthognathic Surgery; J.C. Posnick

• **Figure 31-12** A 14-year-old girl who was born with velocardiofacial syndrome. She had mild learning disabilities, an adequately functioning velopharyngeal valve, and mild sibilant distortions with articulation as a result of malocclusion. She had a long face growth pattern that included a skeletal Class II anterior open-bite malocclusion. She underwent orthodontic treatment that included four bicuspid extractions and orthognathic surgery. The patient's procedures included Le Fort I osteotomy (anterior vertical intrusion with counterclockwise rotation) and bilateral sagittal split ramus osteotomies (horizontal advancement with counterclockwise rotation). **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

Continued

• **Figure 31-12, cont'd C,** Oblique views before and after reconstruction. **D,** Profile views before and after reconstruction.



• **Figure 31-12, cont'd E,** Occlusal views before and after reconstruction. **F,** Articulated dental casts that indicate analytic model planning. **G,** Lateral cephalometric radiographs before and after reconstruction.

- Controversies and Unresolved Issues
- Conclusions

The successful reconstruction of cleft lip and palate is inextricably connected with orthodontic care and skeletal surgery. The negative effects of the primary surgical repair of cleft palate during childhood have been known for the past 200 years.

In 1880, the pioneer orthodontist Normal W. Kingsley stated the following in his remarks about surgical operations as a means of correcting cleft palate: "Although the practice [of cleft palate repair] has been tested in thousands of cases by the most eminent surgeons of their time, it has resulted in such uniformity of failure [i.e., severe jaw deformities], that it should have been utterly abandoned years ago."[85]

In 1920, another preeminent orthodontist of his day, Calvin Case, voiced a similar sentiment: "[L]et us hope that the proportion of [cleft palate] surgical failures will be greatly lessened in the future and that well-informed, honest surgeons … accept only the most favorable cases with a determination to follow them through with proper interest."[16]

In 1965, Vilray Kazanjian, who was a leading maxillofacial surgeon of the first half of the twentieth century, reminded us that "the relative value of surgery to repair a cleft palate has been intelligently questioned for over 150 years."[83]

Facial Growth Implications of Cleft Palate Repair in the Infant with Unilateral Cleft Lip and Palate

Effects of Cleft Palate Repair in Infancy

The management of individuals with unilateral cleft lip and palate (UCLP) presents specific clinical challenges for the maxillofacial surgeon, the orthodontist, and the restorative dental team. Orthognathic surgery is a procedure that should be considered as part of the treatment algorithm for patients with UCLP. Ross completed a multicenter, long-term facial growth study to assess the need for orthognathic surgery among individuals born with complete UCLP who had undergone primary lip and palate repair during

childhood. He concluded that, even by the most conservative standards and in conjunction with maximum compensating orthodontic camouflage maneuvers, at least 25% of adolescents with UCLP required orthognathic surgery to achieve even the limited objective of a neutralized occlusion.[148] His research indicated that only 25% of adolescents with UCLP had near-normal maxillary growth and that another 50% were in a borderline category with some degree of maxillary hypoplasia. Ross stated that individuals who were born with a cleft lip and palate have an intrinsic deficiency in the midfacial skeleton that is made worse by operations. More recently, Mulliken and colleagues reviewed the prevalence of Le Fort I osteotomies among patients with cleft lip and palate who were treated at Boston Children's Hospital.[55] They found that 48% of UCLP patients who underwent repair in infancy later required orthognathic surgery. The study also showed that the need for orthognathic surgery is dependent on the severity of the cleft type as well as the number and extent of previous operative procedures. Similarly, The Hospital for Sick Children in Toronto, Ontario, Canada, found that 48.3% of their patients (i.e. treated since infancy) with complete UCLP required orthognathic surgery. When they looked at all patients with UCLP who were referred to their center, they found that 59.4% needed jaw surgery.[27] A retrospective cohort study of five prominent cleft palate centers in North America compared the maxillomandibular relationships of individuals with non-syndromal complete UCLP (n = 169).[63] The one center that incorporated primary alveolar bone grafting showed especially poor maxillary growth, with 66% of its patients requiring orthognathic surgery. Interestingly, at the one center in which a single surgeon performed all of the surgeries with the use of a more delayed approach to cleft palate repair and whose patients underwent no revisions until they were 14 years old showed the lowest need for orthognathic surgery at less than 25%.

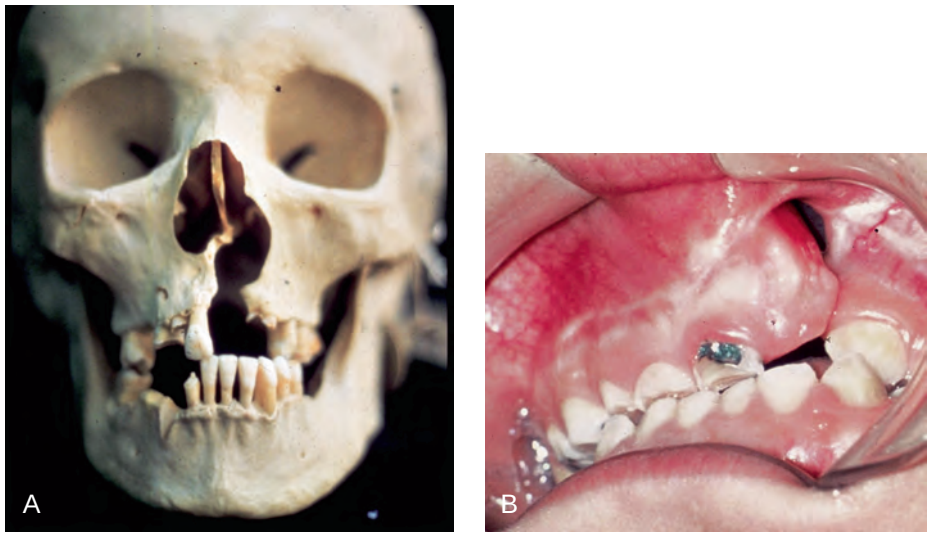
Saperstein and colleagues described the facial growth of children with complete clefting of the primary palate (i.e., the lip through the incisal foramen) but with an intact secondary palate (i.e., the incisal foramen through the uvula).[151] This was a retrospective, cross-sectional analysis of non-syndromal patients with unilateral complete clefting of the primary palate as compared with those with unilateral complete clefting of both the primary and secondary palates. Angular and linear measurements of the midfacial region were made on lateral cephalograms. The study groups included those with unilateral complete clefting of the primary palate (n = 25) and those with unilateral complete clefting of the primary and secondary palate (n = 18). The study documented that individuals with a cleft of only the primary palate who underwent lip repair during infancy typically had a normal or even slightly forward maxillary position as compared with age-matched controls. This was in contrast with children with a cleft of both the primary and secondary palates who underwent lip repair followed by palate repair before they were 1 year old; this group showed a high incidence of maxillary deficiency. The study clarified that the cleft palate repair carried out before 1 year of age—and not the cleft lip repair itself—was responsible for the high incidence of midface hypoplasia.

Effects of Achieving Bone Fusion Across the Cleft Alveolus during Infancy

Reconstruction of the alveolar process in patients with UCLP is an essential part of cleft care. Accomplishing this goal provides support for the alar base of the nose; the teeth in the cleft region; and the periodontium that surrounds those teeth (Figs. 32-1 and 32-2). There are three basic methods that have been described for the closure of the cleft alveolus: 1) primary bone grafting; 2) secondary bone grafting; and 3) gingival periosteoplasty (GPP).[56] The method of primary bone grafting is now generally recognized to result in severe midface growth disturbance and has therefore been universally abandoned throughout the world.[63,148] The use of secondary (mixed dentition) bone grafting is generally recognized as an effective method to avoid the problem of additional midface growth disturbance and to successfully achieve support for the alar base; to provide bone for the eruption of the canine through the grafted cleft site; and to establish effective periodontal support (Figs. 32-3 through 32-6).[1]

The technique of GPP was first described by Skoog in 1965 as a method to achieve fusion across the cleft alveolus at the time of lip repair. The goal was to "remove" the cleft during infancy with the hope that no harm would result.[156] Millard included the use of the Latham device to position the alveolar ridges close to one another before going forward with the GPP procedure at the time of lip repair.[105,106] Grayson and Cutting later proposed the use of a nasoalveolar molding device before the GPP and primary lip repair to accomplish the same alveolar ridge fusion. Several studies confirm that the GPP procedure has a high osteogenic potential that results in the deposition of bone to achieve successful fusion of the alveolar ridge. Unfortunately, clinical studies do not confirm sufficient bone fill to consistently allow for the eruption of the canine through the ridge and to provide ideal periodontal support. Since the late 1970s, clinical studies have been carried out to assess the long-term effects of GPP on midfacial growth in cleft patients.

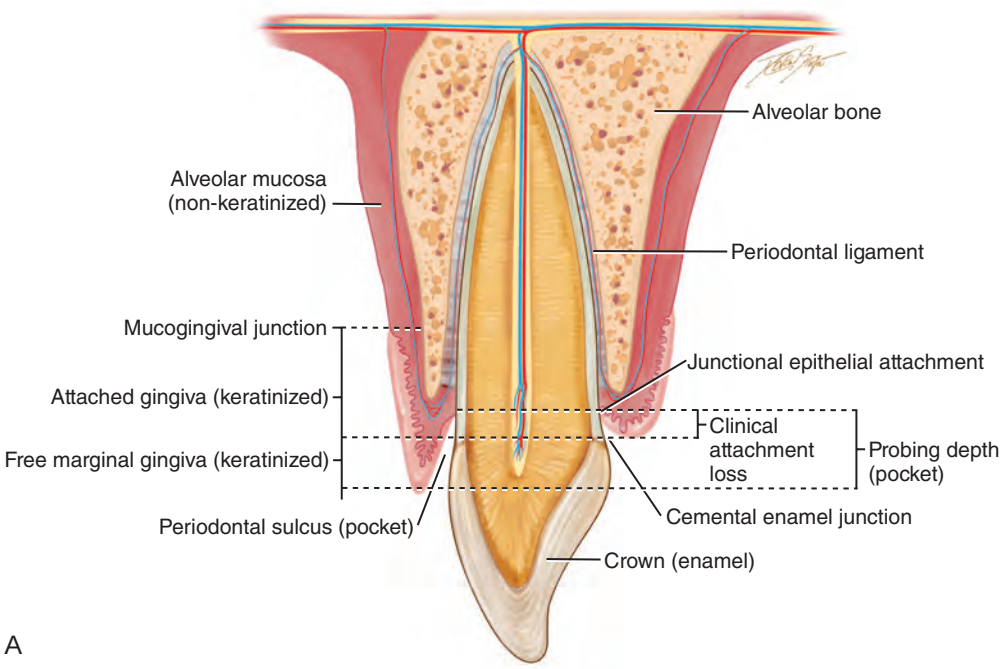
In 1999, Millard and colleagues used serial dental casts to evaluate the effects of GPP on maxillomandibular relationships.[106] They found a greater frequency of anterior crossbite in the GPP group than in the non-GPP group. They also confirmed that the GPP group had a shorter anteroposterior length of the maxilla as compared with the non-GPP group at 6 years of age. Similar findings of poor midface growth have been documented by Berkowitz and colleagues,[9] Matic and Powers,[99] and others.[70,169] In 2005, Renkielska and colleagues evaluated the impact of GPP on occlusal relationships with the use of the Goslon Yardstick occlusal grading system.[143] They found that patients treated with GPP had a poor occlusal relationship and a Goslon Yardstick score of 4 and 5, thus indicating need for

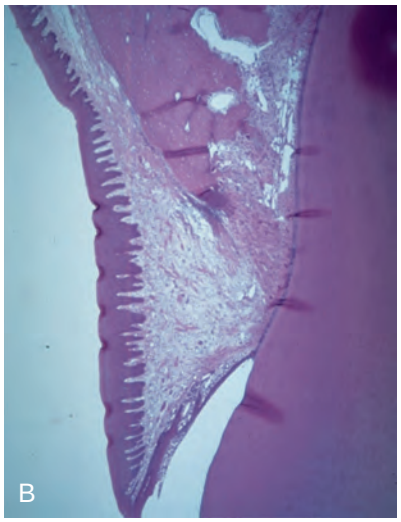


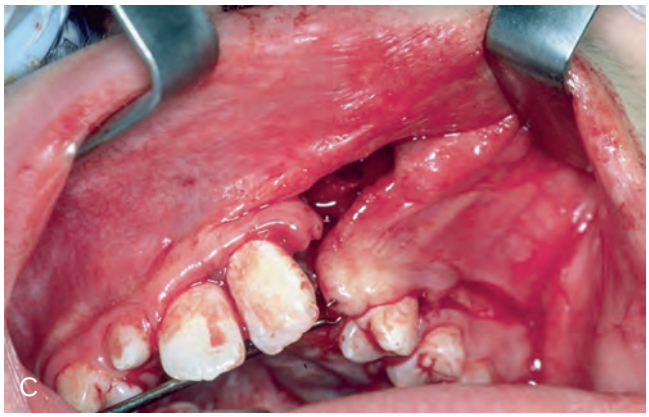
• **Figure 32-1 A,** The maxillofacial skeleton of an adult with unrepaired unilateral cleft lip and palate (UCLP) is shown. Typical UCLP deformities of the hard palate, the alveolus, the nasal septum, the floor of the nose, the nasal spine, and the pyriform rims are demonstrated. **B,** An occlusal view of a child born with UCLP who presented during the mixed dentition with a residual alveolar/palatal skeletal defect and a labial and palatal oronasal fistula is also shown.

• **Figure 32-2** A 6-year-old boy who was born with a UCLP is shown after soft tissue lip and palate repair in infancy. **A,** Frontal and **B,** oblique facial and computed tomography scan views during the mixed dentition demonstrate residual cleft skeletal defects and deformities that were present before grafting and fistula closure.

• **Figure 32-3** An example of the suboptimal management of a unilateral alveolar/palatal cleft. A child who was born with UCLP underwent soft tissue lip and palate repair during infancy. She underwent orthodontic treatment and achieved a satisfactory overjet and overbite. The alveolar/palatal cleft skeletal defects and the residual labial and palatal oronasal fistula were ignored. The maxillary lateral incisor tooth was inadequate and required extraction. The canine erupted adjacent to the cleft, and the dental gap was orthodontically retained. Dental rehabilitation was accomplished with a three-unit bridge to manage the cleft–dental gap. Limited periodontal (bone) support of the cleft-adjacent teeth (the canine and the central incisor) resulted in a periodontic–endodontic problem with a loss of the canine and poor support of the central incisor. These problems would not have occurred had effective bone grafting and fistula closure been carried out during the mixed dentition. **A,** Occlusal and palatal views during the mixed dentition before the full eruption of the canine through the non-grafted alveolar cleft. **B,** Occlusal and palatal views are also shown during orthodontic alignment (extraction of right bicuspid was carried out). **C,** Occlusal view at the completion of orthodontic alignment. A periapical radiograph indicates limited bony support of the cleft-adjacent teeth. **D,** An occlusal view is next shown after the placement of a three-unit bridge across the cleft–dental gap. A periapical radiograph confirms that, after several years, a periodontal–endodontic problem resulted in irreversible injury to the cleft-adjacent canine.

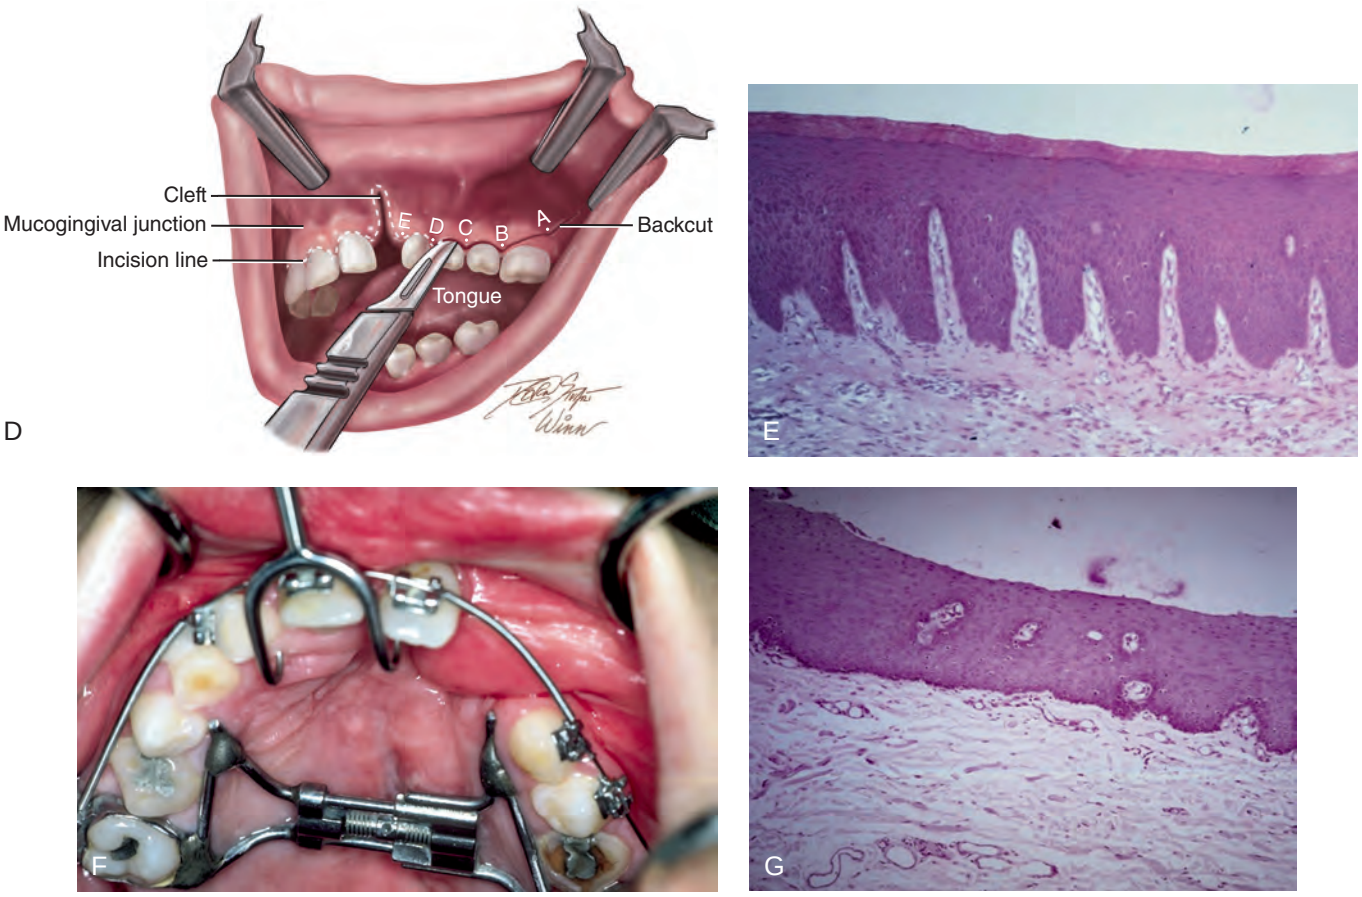






• **Figure 32-4** The importance of maintaining keratinized tissue adjacent to the cervical margin of each tooth for long-term periodontal health cannot be overemphasized (see Chapter 6). **A,** Illustration of a cross-section of dentoalveolar anatomy that indicates the location of the gingiva (keratinized mucosa) adjacent to the tooth surface. **B,** Low-power histomicrograph cross-section of the dentoalveolar anatomy that indicates the microscopic character of the keratinized mucosa adjacent to the tooth surface. Just deep to the keratinized epithelium rete pegs, organized fibrous tissue can be seen. **C,** Intraoperative view of an elevated mucogingival flap advanced anteriorly for the closure of the labial aspect of the cleft oronasal fistula. The flap brings the gingiva into the region where the canine will erupt.

Continued



• **Figure 32-4, cont'd** **D,** Illustration of incision placement for the elevation of the mucogingival flap. The flap splits the attached gingiva posteriorly adjacent to the first molar so that the advancing flap brings keratinized tissue into the cleft site without denuding the attached gingiva from the posterior teeth. **E,** Low-power histomicrograph that demonstrates keratinized epithelium, organized fibrous tissue, and rete pegs. **F,** Palatal view of a patient with UCLP during the mixed dentition. This patient underwent the closure of an oronasal fistula using a buccal "finger" flap by another surgeon. This is *not* the preferred way to rearrange the intraoral tissue for fistula closure; the labial vestibule is destroyed, and non-keratinized buccal mucosa is brought into the region where the canine will erupt. **G,** Low-power histomicrograph of non-keratinized buccal mucosa. Note the thin layer of non-keratinized epithelium with the underlying loose areolar connective tissue. *Part D modified from an original illustration by Bill Winn.*

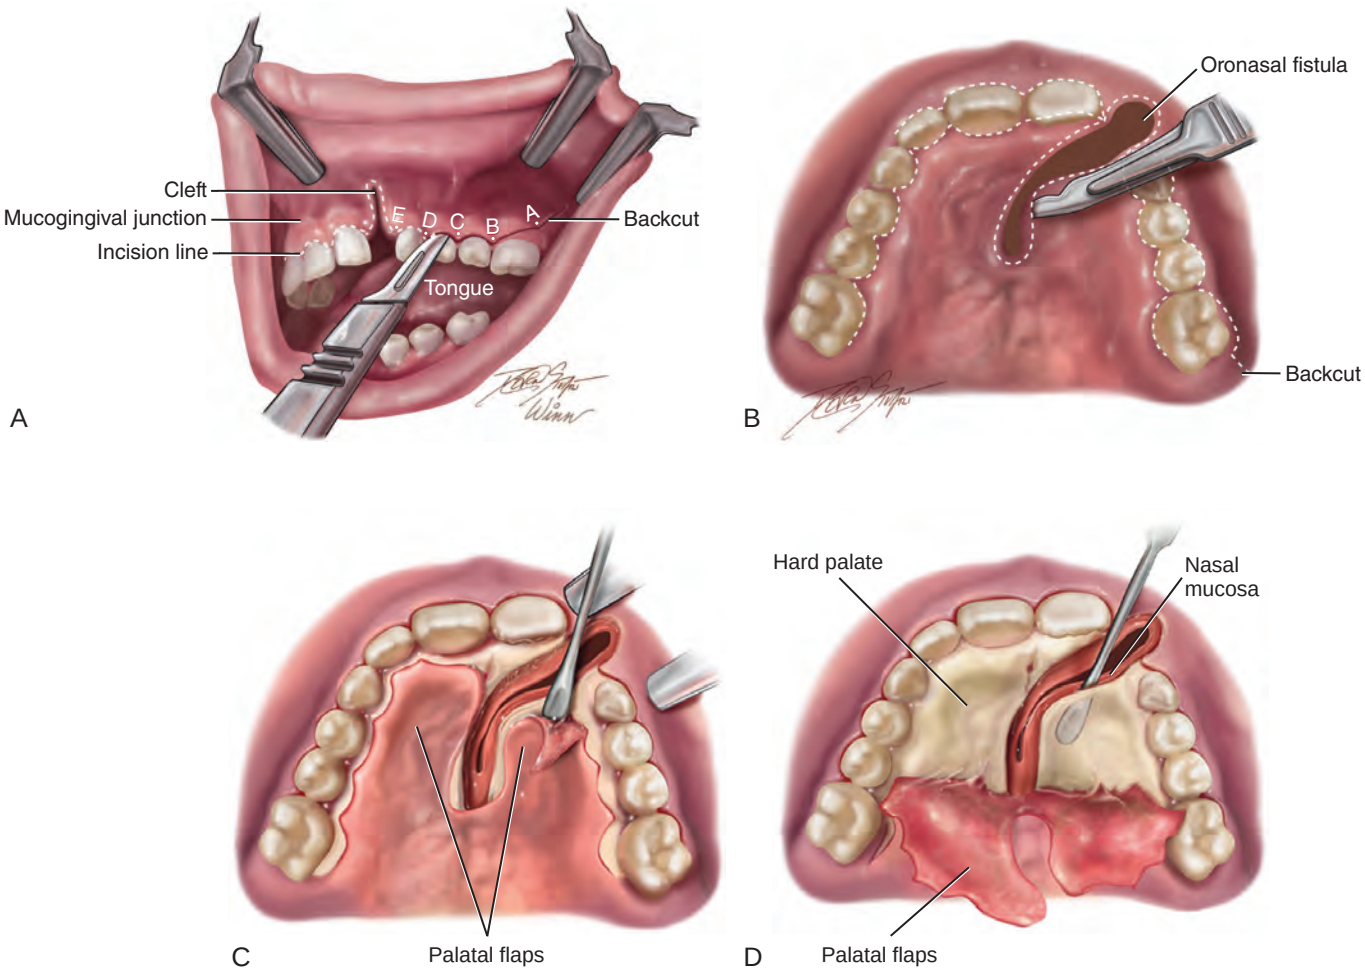
orthognathic surgery. They reaffirmed that the inclusion of the alveolar process in the primary lip repair increased severe occlusal maldevelopment.

More recently, Hsieh and colleagues completed a retrospective clinical study to evaluate the effects of GPP on facial growth in patients with UCLP.[74] Sixty-two consecutive patients with non-syndromal complete UCLP with records from when they were 5 years old were included in the study. All of the patients had received nasoalveolar molding treatment before primary lip repair. Those individuals who underwent GPP at the time of lip repair (n = 26) were placed in one group. Those that did not undergo GPP at the time of lip repair (n = 36) were placed in another group. Cephalometry was used to evaluate facial growth at 5 years of age in the two treatment groups. GPP was found to have significant negative effects on the maxillary position (i.e., diminished horizontal projection), the intermaxillary position (i.e., negative overjet), the maxillary length, and the maxillary alveolar length at the age of 5 years. The authors concluded that, in patients with UCLP, the sagittal growth of the maxilla was significantly adversely affected by the GPP procedure. As a result of their study, the Chang Gung Cleft Center no longer uses the GPP technique.

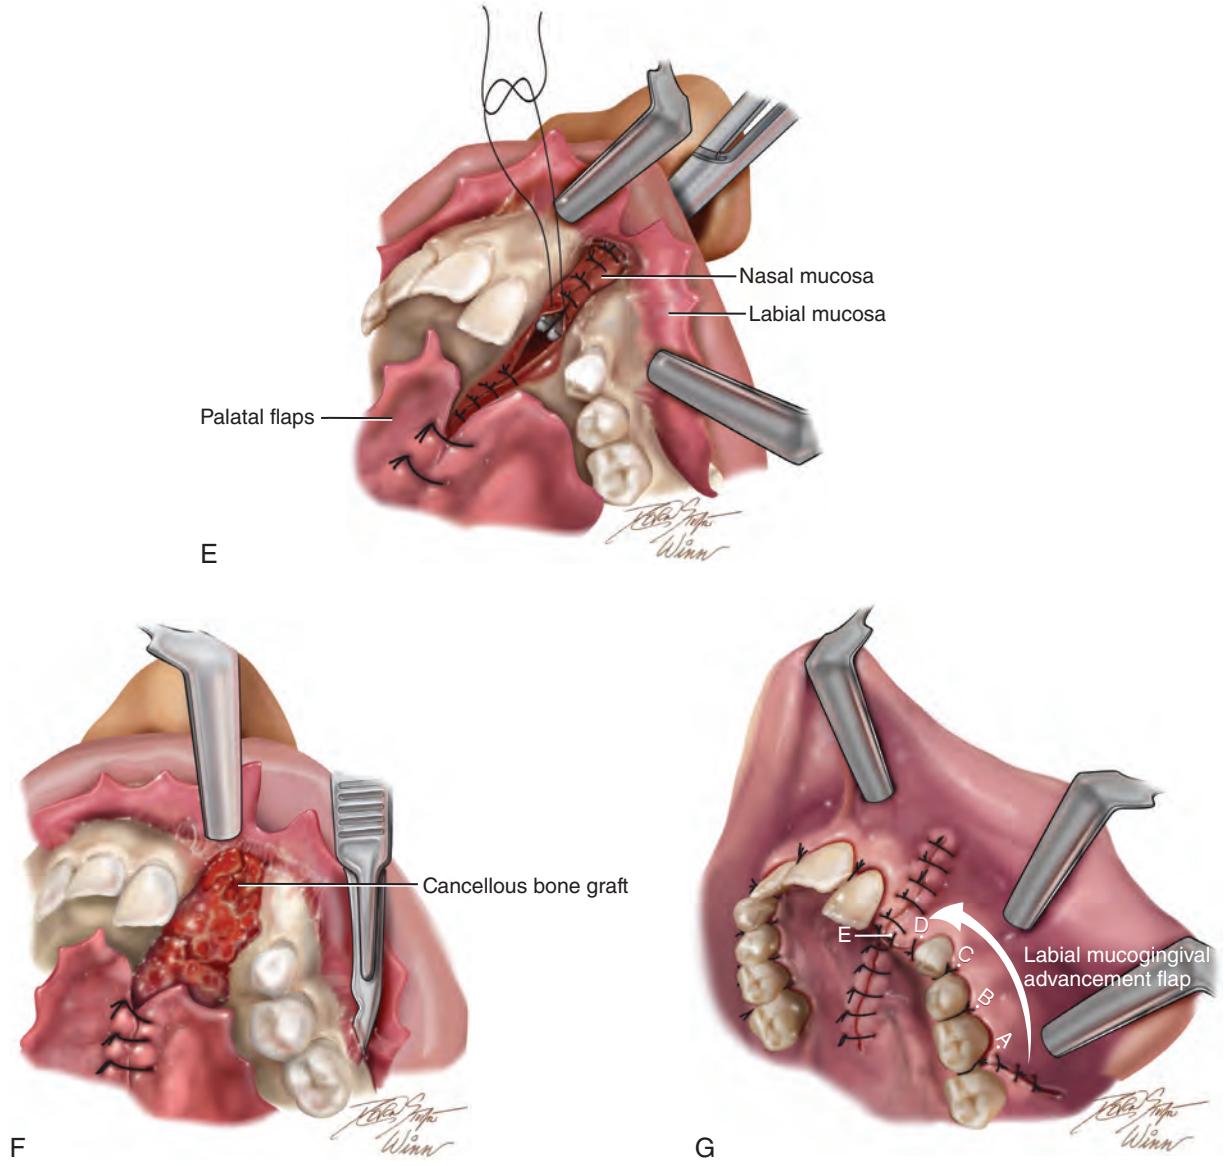
Coordinated Team Approach

Care of the patient with UCLP is best delivered by an integrated group of specialists who evaluate and provide comprehensive definitive care. It is no longer acceptable for individual practitioners (e.g., surgeons, orthodontists, restorative dentists, speech pathologists, otolaryngologists) to carry out extended treatment without considering all aspects of the patient's care and without discussing options with members of the team.[82,90]

A frequent road block to successful reconstruction and dental rehabilitation of the midface-deficient adolescent with UCLP—especially in those who present with other residual clefting problems (see the section about residual deformities later in this chapter)—is disagreement between clinicians about the indications, the most effective techniques, and the timing of intervention.[8,104,123] The surgeon, the orthodontist, the dental and medical team, and the



• **Figure 32-5** Illustrations of basic technique for bone grafting and the management of residual oronasal fistula during the mixed dentition of a child with a UCLP. If required, orthodontic expansion to correct the arch width precedes mixed-dentition bone grafting. **A,** A view of the left labial mucogingival incision in progress. **B,** Attention is turned to the sharp palate for the separation of the oral and nasal mucosa at the site of the fistula and then the elevation of the flaps. **C,** Subperiosteal elevation of the palatal flaps. **D,** With the palatal flaps elevated, the nasal mucosa is separated from the floor of the nose on each side. Left and right labial flaps have already been elevated. The nasal mucosa is further separated from the bony surface along the distal aspect of the central incision for later closure. *Part A modified from an original illustration by Bill Winn.* *Continued*



• **Figure 32-5, cont'd** **E,** Suturing of the nasal flaps for watertight closure is in progress. A hemostat is placed through the left nostril to demonstrate the partially sutured nasal floor. The palatal flaps have been sutured together for fistula closure. **F,** After the nasal flaps are sutured, iliac cancellous bone graft is packed into the palatal, alveolar, and floor-of-the-nose skeletal defects. **G,** Left and right labial and palatal flaps are advanced for watertight closure. By advancing the left labial mucogingival flap, the keratinized tissue has been placed over the alveolar ridge, where the canine will eventually erupt. This is accomplished by splitting the attached gingiva at the last molar.

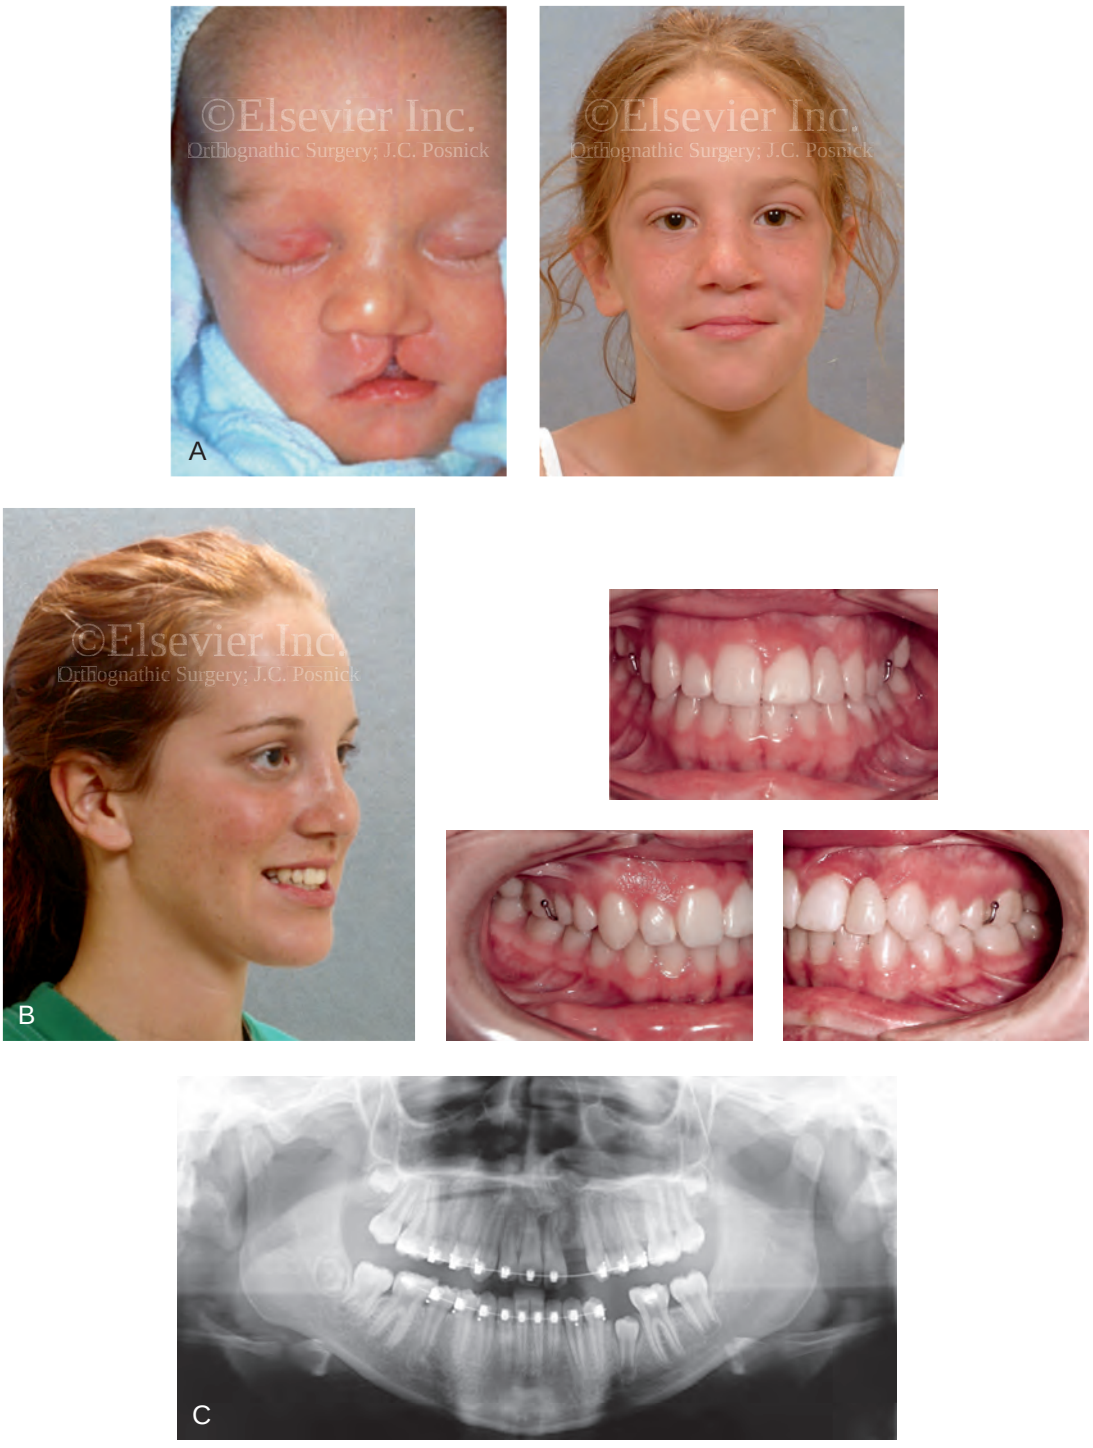
patient and his or her family must first agree about the dental, occlusal, speech, upper airway, and aesthetic objectives; only then can effective treatment go forward.

The advantage of coordinated care was confirmed by the Eurocleft Study, which found a lack of association between high-intensity disjointed treatment and favorable results. In other words, the greater the number of operations and the greater the number of years of orthodontic appliances worn (i.e., heavy burden of care), the worse the outcome.[25,108]

Treatment Protocol

Patients who present with a UCLP jaw deformity after being referred for possible orthognathic surgery are seen at a minimum by an orthodontist, an orthognathic surgeon, an otolaryngologist, and a speech pathologist. Additional consultations with other dental (ex. prosthodontist, pediatric or general dentist, periodontist) and medical (i.e., sleep specialist, geneticist) specialists are carried out as indicated. For the evaluation of a cleft dentofacial deformity, records and tests should include medical-quality photographs, cephalometric and dental radiographs, dental models, direct facial measurements, speech and velopharyngeal (VP) assessment (e.g., nasoendoscopic instrumentation), and a thorough evaluation of the upper airway.

The primary surgeon not only performs repair of the cleft lip and palate and corrects VP insufficiency but also plays a role in directing the patient's overall care. If the primary



• **Figure 32-6** A 16-year-old girl was born with van der Woude syndrome, including UCLP and lower lip pits. She has been managed by this surgeon since her birth. She underwent lip and palate repair during her early childhood, which was followed by successful bone grafting and fistula closure during the mixed dentition. She had normal maxillary growth and underwent standard orthodontic treatment with the maintenance of the cleft–dental gap. She underwent an open rhinoplasty that included the use of a septal cartilage (caudal strut) graft when she was 15 years old. There is sufficient bone volume and attached gingiva for a dental implant, which is planned for when she is 18 years old. **A,** Facial views at the time of birth and during the mixed dentition, just before alveolar/palatal bone grafting. **B,** Facial and occlusal views taken when the patient was a teenager after rhinoplasty and before dental implant placement. A removable retainer that includes the missing lateral incisor is in place. **C,** Panorex image taken when the patient was a teenager during orthodontic treatment indicates successful bone grafting of the alveolar cleft.

cleft surgeon is not trained in skeletal procedures, then a timely and seamless transition to the orthognathic maxillofacial surgeon should occur. The surgeon who is caring for the patient with clefting and a skeletal deformity should have a fundamental understanding of the patient's dental, speech, upper airway, and aesthetic needs. He or she should request consultation with appropriate specialists, evaluate the clinical information, and be prepared to perform orthognathic and intranasal procedures.

The orthodontist provides interceptive treatment during the mixed dentition in association with bone grafting and carries out definitive orthodontic treatment in conjunction with orthognathic surgery, when indicated. From the mixed dentition phase, the cleft orthodontist should recognize the patient with UCLP who may require orthognathic surgery.* The institution of extensive camouflage (dental compensatory) treatment is likely to jeopardize periodontal health and lead to late dental relapse. Proceeding with a compromised (camouflage) orthodontic approach should only be entered into with full disclosure to the family and other treating clinicians.

Before orthognathic surgery, a speech pathologist evaluates the patient to characterize VP function and to identify articulation errors that result from the cleft palate jaw deformity and the dental malocclusion (see Chapter 8). A baseline evaluation is important, because VP function may deteriorate after maxillary advancement. A nasoendoscopic guided speech assessment is useful to provide maximum objective data.[180] VP closure that is adequate before surgery may become borderline afterward, and VP closure that is borderline may become inadequate. Studies document that only a small percentage of patients require a primary pharyngeal flap or flap revision after maxillary advancement.[19,20,57,60,79,86,91,95,102,125,170,180] Articulatory distortions that result from malocclusion are also identified and cause-and-effect relationships are determined. The successful orthodontic and surgical correction of crossbites, open bite, cleft–dental gaps, negative overjet, and residual oronasal fistulas represents the most effective way to correct the identified articulation distortions (see Chapter 8). Unfortunately, the use of "oral–motor therapy" is still often applied to manage both jaw-deformity–related articulation errors and VP insufficiency; however, this type of treatment has not been proven beneficial for dynamic speech.

A thorough evaluation of the upper airway is conducted to assess for areas of obstruction (see Chapter 10). Studies suggest an increased prevalence of sleep-disordered breathing and obstructive sleep apnea in patients with cleft palate, especially in the presence of Robin sequence. A formal sleep study (i.e., an attended polysomnogram) is performed if there is a suggestion of obstructive sleep apnea (see Chapter 26). If indicated, simultaneous intranasal procedures (e.g., septoplasty; reduction of the inferior turbinates; recontouring of the nasal apertures, the floor of the nose, and the anterior nasal spine) should be carried out at the time of orthognathic surgery (see Chapters 10 and 15).[150]

Discussions among the treating medical and dental consultants, the patient, and the family clarify the need for and the extent of orthognathic and intranasal procedures. The overall plan for speech, jaw, upper airway, and dental rehabilitation and for the enhancement of facial aesthetics is agreed upon before the initiation of treatment.

Timing of Orthognathic Surgery

Definitive correction of the jaw deformity is best carried out when the skeleton is mature and before the patient finishes high school.[82,90] Maxillofacial growth is generally complete between the ages of 14 and 16 years in girls and 16 and 18 years in boys. However, skeletal growth is variable and may be further gauged by an analysis of sequential lateral cephalometric radiographs taken at 6-month intervals (see Chapter 17). The patient's and the family's preferences for the timing of the operation on the basis of psychosocial and functional needs are also taken into account.

As early as 1986, investigators showed that, if maxillary advancement is performed during the mixed dentition in a patient with a cleft palate, then another orthognathic procedure will be necessary for definitive correction after skeletal maturity is reached.[181-184] All research to date indicates that a Le Fort I osteotomy carried out during the mixed dentition in a patient with clefting—whether with standard or distraction osteogenesis (DO) techniques—results in no further horizontal maxillary growth (see the controversies section later in this chapter).[21,41,40,75]

Residual Deformities in the Adolescent with Unilateral Cleft Lip and Palate

Correction of the residual skeletal, soft-tissue, and dental deformities in the adolescent patient with UCLP challenges the ingenuity and skill of the orthognathic surgeon and the cleft team. The central deformity is maxillary hypoplasia (Figs. 32-7, 32-8, and 32-9), and it is frequently combined with residual oronasal fistula, bone defects, intranasal obstruction, soft-tissue scarring, and, occasionally, VP dysfunction (Figs. 32-10 through 32-21).[84,167] In addition, the maxillary lateral incisor at the cleft site is usually congenitally absent or deficient, thereby resulting in a cleft–dental gap. Secondary deformities of the nose, the mandible, and the chin region are also common.

The prevalence of these residual clefting deformities in mature patients with UCLP varies widely depending on the primary cleft surgeon's philosophy, available expertise, the individual's intrinsic biologic growth potential, and the patient's and family's interests. Published clinical surveys of individuals who were born with complete UCLP and treated at established cleft centers provide insight into alveolar cleft management. The studies indicate that, despite a

• **Figure 32-8** A 20-year-old man was born with UCLP on the right side. Primary lip and palate repair were carried out at another institution. He was referred to this surgeon and underwent successful bone grafting and fistula closure during the mixed dentition. He underwent orthodontic closure of the cleft–dental gap and limited alignment by the time he was 14 years old. Final orthodontic decompensation was later carried out in combination with orthognathic surgery when he was 19 years old. The patient's procedures included maxillary Le Fort I osteotomy (horizontal advancement, vertical shortening, midline correction, cant correction, and clockwise rotation) with interpositional grafting; sagittal split ramus osteotomies (counterclockwise rotation and asymmetry correction); osseous genioplasty (horizontal advancement); and septoplasty, inferior turbinate reduction, and recontouring of the floor of the nose. **A,** The patient is shown during the mixed dentition after successful bone grafting and fistula closure. **B,** Frontal views in repose before and after reconstruction. **C,** Frontal views with smile before and after reconstruction.

Prior to surgery with residual cleft defects

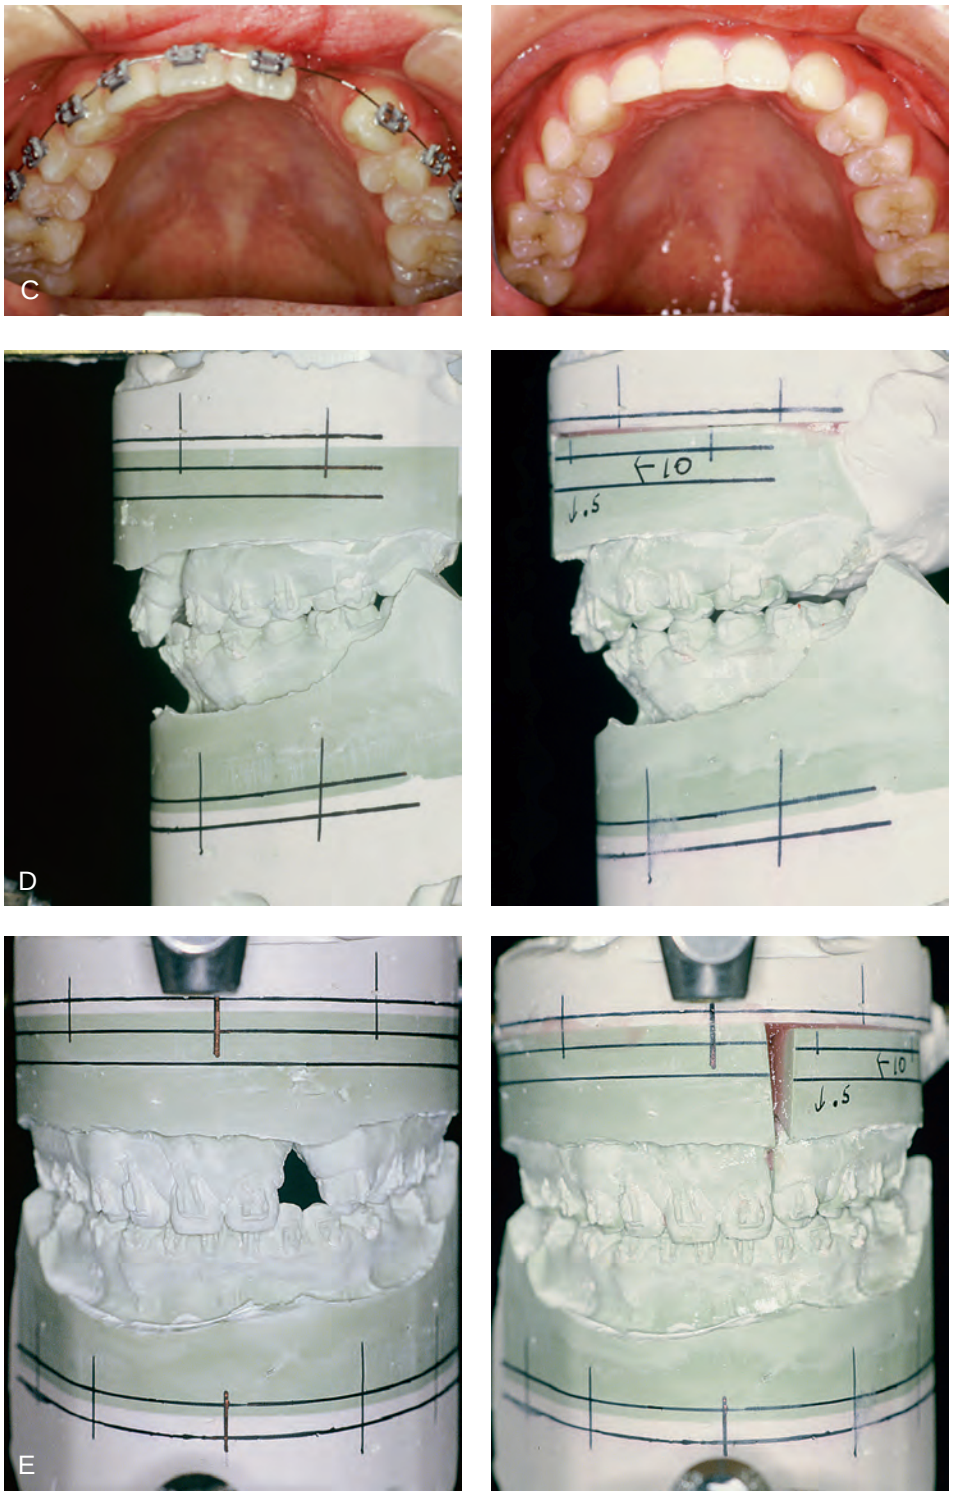
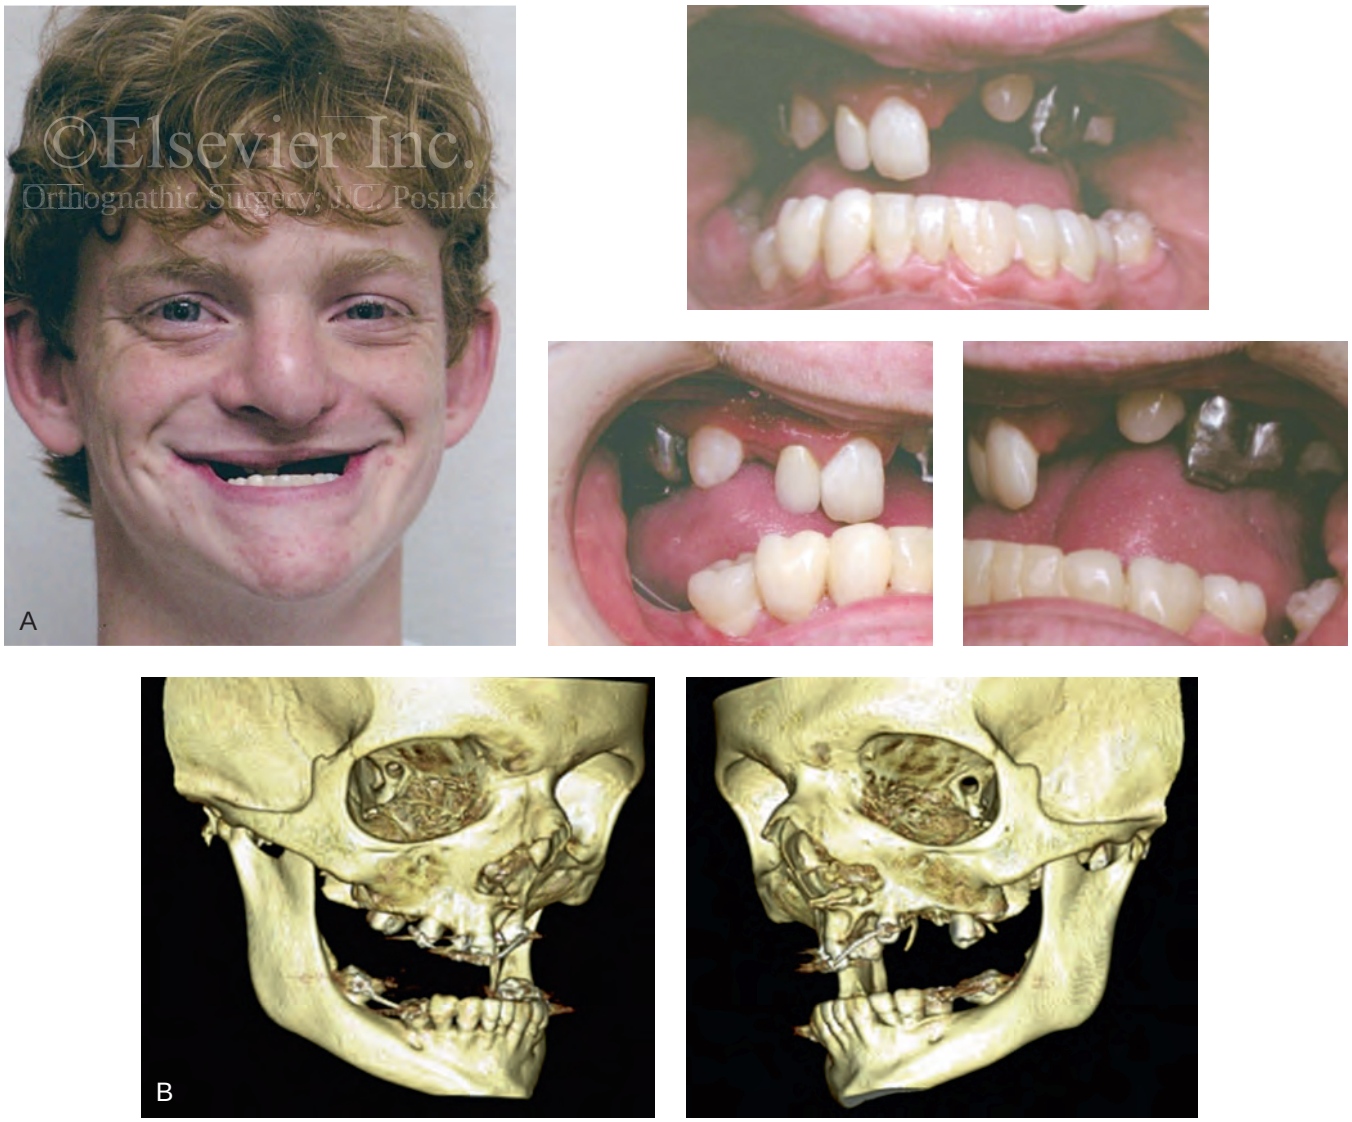
• **Figure 32-20** A 17-year-old girl who was born with UCLP. She underwent lip and palate repair during childhood, but she did not undergo effective bone grafting during the mixed dentition. The lateral incisor is not present at the cleft site. She was referred to this surgeon and underwent a combined orthodontic and orthognathic surgical approach. The maxilla had good horizontal projection and vertical height. Of the options available to manage the residual upper dentoalveolar needs, a right posterior segmental osteotomy was completed to close the oronasal fistula, the alveolar defect, and the cleft–dental gap. **A,** Frontal views with smile before and after reconstruction. **B,** Occlusal views with orthodontics in progress and after reconstruction. *Continued*



• **Figure 32-20, cont'd C,** Palatal views with orthodontics in progress and after reconstruction. **D** and **E,** Articulated dental casts that indicate analytic model planning.



• **Figure 32-21** A teenage boy who was born with ectodermal dysplasia and complete UCLP on the left side. He underwent lip and palate closure during infancy. There are multiple congenital missing teeth in each arch. He was referred to this surgeon for evaluation when he was 14 years old. He retains only six long-term useful teeth in the maxilla (first and second molars) and displaced left and right canines. The maxilla is vertically and horizontally deficient. The mandible has satisfactory symmetry and horizontal projection. The patient underwent evaluations by specialists, including an orthodontist, a prosthodontist, a periodontist, a surgeon, a speech pathologist, an otolaryngologist, and a geneticist. Reconstruction and dental rehabilitation were felt to require the surgical repositioning of the maxilla followed by an overdenture. In the mandible, crown and bridge rehabilitation would be carried out. The prosthodontist requested 18 mm of horizontal advancement and 14 mm of vertical lengthening of the maxilla. A two-stage approach to maxillary reconstruction was undertaken.

Stage I surgery included the following: 1) nasotracheal intubation; 2) Le Fort I osteotomy with down fracture and disimpaction; 3) septoplasty and inferior turbinate reduction; 4) application of a MED I external distraction device; and 5) securing of the MED I device to a prefabricated in-place chrome cobalt appliance fixed to the maxillary dentition. Successful **outpatient distraction** of the maxilla to the preferred position was accomplished over a 10-day time frame.

Stage II surgery involved the patient's return to the operating room for the following: 1) awake fiber-optic nasotracheal intubation; 2) removal of the MED I device; 3) harvesting of the anterior iliac corticocancellous graft; 4) reopening of the circumvestibular incision; 5) securing a prefabricated splint to the maxilla and then applying intermaxillary fixation (18 mm of advancement); 6) rotation of the maxillomandibular complex to achieve the desired vertical dimension (14 mm of lengthening); 7) application of plate and screw fixation to the maxilla; 8) crafting and inset of corticocancellous grafts to the left and right anterior maxilla; and 9) plate and screw fixation of each graft to the native maxilla. **After 6 weeks**, the maxilla achieved initial bone healing. The patient returned to a more regular diet and sports activities at that time. **Six months postoperatively**, the patient underwent a pharyngeal flap procedure to achieve velopharyngeal competence and an open rhinoplasty procedure that included a rib cartilage (caudal strut) graft. **Dental rehabilitation** included fixed bridgework in the mandibular arch and overdenture construction for the maxilla. **A,** Frontal and occlusal views when the patient was 14 years old. **B,** Computed tomography scan views that indicate the extent of maxillary hypoplasia.

cleft team's best efforts, a number of children will not make themselves available for mixed-dentition grafting (i.e., before the eruption of the cleft side canine). In addition, a percentage of those who do undergo such procedures will have problems with grafting and require other means of reconstruction and dental rehabilitation. Williams and colleagues documented that, in the United Kingdom, only 84% of children with complete UCLP arrived for mixed-dentition grafting.[177] McIntyre and colleagues documented that only 75.4% of Scottish children with complete UCLP were grafted during the mixed dentition.[103] Daskalogiannakis and colleagues documented that, at The Hospital for Sick Children in Toronto, children with complete UCLP underwent mixed-dentition grafting only 56.1% of the time.[27] On a more encouraging note, Felstead and colleagues documented a 94% rate of radiographically successful mixed-dentition bone grafting in a consecutive series of children with UCLP or bilateral cleft lip and palate (BCLP) who were treated by a single surgeon (n = 53 alveolar cleft sites).[39] Despite a clinician's preferred approach to cleft management during infancy, childhood, and early adolescence and despite that clinician's best efforts, a subgroup of patients with UCLP patients will present during or after adolescence with multiple cleft-related problems that may include the following:

1. *Maxillary hypoplasia.* The maxilla is often vertically short and canted (upward on the cleft side), and the maxillary dental midline is usually shifted off of the facial midline toward the clefted side. Arch-width deficiency that results in a dental crossbite is usually present. The hypoplastic maxilla is retruded in the horizontal plane, thereby resulting in a concave midface profile. There will be an Angle Class III malocclusion and negative overjet. In general, the greater and lesser maxillary segments vary with regard to the degree of dysplasia, thereby making it difficult to achieve a satisfactory occlusion and facial appearance by repositioning the maxilla in one unit. Separation in two segments (through the cleft) with differential repositioning is often required for the management of the arch shape, even if successful mixed-dentition grafting was accomplished.
2. *Residual oronasal fistula.* Despite a preference for oronasal fistula closure during the mixed dentition, the UCLP candidate for orthognathic surgery will often have residual labial and palatal fistulas. Previous attempts at closure may have failed. Furthermore, buccal (non-keratinized) mucosa may have been placed over the cleft site, thereby resulting in a lack of attached gingiva (keratinized mucosa) in the tooth-bearing region and a loss of vestibular depth.
3. *Residual bony defects.* In the patient with UCLP who has not been successfully or adequately grafted during the mixed dentition, a bony defect not just at the alveolus but throughout the hard palate and the floor of the nose may exist. This results in an inferiorly displaced or deficient floor of the nose and nasal sill with rotation of the anterior nasal spine and the septum toward the cleft. There may also be inadequate alveolar bony, gingival, and periodontal support for the teeth adjacent to the cleft.
4. *Cleft–dental gap.* Studies confirm that, approximately 93% of the time in patients with UCLP, the lateral incisor is either congenitally absent or inadequate at the cleft site.[163,164] A hypoplastic lateral incisor or a supernumerary tooth may be present adjacent to the cleft, but it will have inadequate root development. Orthodontic closure of this dental gap by bodily moving the canine tooth into the bone-grafted lateral incisor location is generally considered the preferred approach. For a variety of reasons, this may not have occurred at the time of referral for orthognathic surgery. At times, there is mesial angulation of the canine (i.e., crown tipped) into a marginally grafted or non-grafted cleft site, while the apex of the root remains distal. The result may be a full or partial dental crown gap at the cleft site between the central incisor and the canine but with an even greater separation of the roots.

NOTE: There are a variety of reasons why the teenaged or adult patient may present with a cleft (lateral incisor) dental gap, including the following: 1) the patient may have "fallen through the cracks" without undergoing mixed-dentition grafting; 2) a grafting procedure may have been carried out but with only limited "graft take"; or 3) the cleft site may have been successfully grafted and followed by a "classic occlusion" approach with the intentional maintenance of the lateral incisor space for later prosthetic replacement. Clinicians that advocate this approach believe that "smile aesthetics" will be more favorable and that maintaining "cuspid protection" during lateral excursions is necessary over "group function."

I have most often found that, for the maxillary deficient individual with UCLP/BCLP with a congenitally absent lateral incisor, either orthodontic gap closure or eventual surgical cleft dental gap closure is preferred for the achievement of an efficient, long-term, low-maintenance dentition. In these cases, favorable smile aesthetics may also benefit from cosmetic enhancements such as crown lengthening or crown modification via dental recontouring or augmentation (i.e., composite resin or veneer buildups).

5. *Chin dysplasia.* The patient with UCLP will frequently suffer with a lifelong history of obstructed nasal breathing and an open-mouth posture. This is often the result of anatomic deformities, including septal deviations, inferior turbinate hypertrophy, an irregular nasal floor, and nasal vestibular stenosis. The presence of a pharyngeal flap since childhood may further

increase an open-mouth breathing tendency. The resulting chin deformities that occur during growth are often characterized by excess vertical length and horizontal retrusion.

6. *Mandibular dysplasia.* True mandibular prognathism or retrognathism is uncommon in the patient with UCLP. However, the need for mandibular osteotomies is frequent. This should be limited to the correction of secondary deformities that result in facial asymmetries and skeletal distortions and the occasional true anteroposterior discrepancy.[88,89,171]
7. *Nasal obstruction and sinus blockage.* Obstructed breathing through the nose and frequent bouts of sinusitis are typical among patients with UCLP. This results from a combination of septal deviation; enlarged inferior turbinates; deformities of the nasal aperture, the floor of the nose, and the anterior nasal spine region; and stenosis of the nasal vestibule.
8. *VP dysfunction.* It has been shown that approximately 20% of patients with a repaired cleft palate will have VP insufficiency by the time they are 5 years old. The adolescent with UCLP who arrives for the evaluation of a cleft jaw deformity may have already undergone a pharyngoplasty with a pharyngeal flap. The planned Le Fort I osteotomy with advancement will alter the upper airway and may also negatively affect VP function, as described later in this chapter.

Orthodontic Considerations in the Patient with Unilateral Cleft Lip and Palate with a Jaw Deformity

The adolescent or adult patient with UCLP who presents with maxillary hypoplasia and ineffective bone grafting performed earlier during his or her childhood will have two maxillary segments separated by a cleft (see Figs. 32-11 through 32-21). Each segment will have a degree of skeletal dysplasia in all three planes of space. From an orthodontic perspective, each segment should be evaluated and treated individually in anticipation of Le Fort I segmental repositioning.

Radiographic assessment is carried out before the orthodontic movement of the teeth adjacent to the bone-deficient cleft site. The Panorex radiograph is useful for assessing the overall morphology of the jaws and teeth as well as tooth angulation. Maxillary occlusal and periapical radiographs through the cleft site or preferably a cone beam computed tomography scan will help with the assessment of the amount of alveolar bone and crestal height surrounding the teeth.

There is variability with regard to the number of permanent incisors and the amount of alveolar bone in the anterior aspect of the UCLP maxilla. A lateral incisor-like tooth is frequently found along the edge of the cleft in the lateral segment. When a poorly formed lateral incisor is present, it should be extracted in the interest of long-term function and dental rehabilitation. Cassolato and colleagues have documented that, in patients with complete UCLP, the lateral incisor on the cleft side is normal and maintained in only 7% of cases.[17] Unerupted supernumerary teeth are also extracted either at the time of bone grafting during the mixed dentition or in conjunction with orthognathic surgery. The central incisor on the cleft side also has a high probability of being malformed.

The decision to extract a fully erupted, normally formed tooth (i.e., the first bicuspid) within the lesser or greater segment depends on the volume and height of the available alveolar bone to house the dental roots adjacent to the cleft and the degree of overall dental crowding within each segment of the jaw. The completion of the first bicuspid extraction in the greater segment, the lesser segment, or both is often required to ensure adequate alveolar bone for leveling and aligning retained teeth without weakening the periodontal support of the teeth adjacent to the cleft and throughout the alveolus (e.g., loss of crestal height, fenestration or dehiscence of the labial plate).

The orthodontist must be aware that the placement of preangulated brackets or artistic positioning bends can displace the roots of the teeth adjacent to the cleft from their alveolar housing with a loss of crestal bone height. A loss of vertical crest height along the cuspid is likely to occur with excessive mesial crown tipping. For these reasons, the orthodontic movement of the cleft-adjacent teeth is accomplished cautiously until the cleft defects are surgically closed, effectively bone grafted, or both.

A potential disadvantage of the modified Le Fort I approach in a patient with UCLP is that the differential advancement of the lesser dentoalveolar segment shifts the preoperative anterior dental gap (i.e., the lateral incisor region) into the posterior region (i.e., the second molar region) (see Fig. 32-5 and discussion later in this chapter). This is no different than the occlusal changes that will occur when the mixed-dentition bone-grafted cleft–dental gap (i.e., with absent lateral incisor) is orthodontically closed by canine substitution. Unfortunately, the mandibular second molar on the cleft side may no longer have an opposing maxillary molar. For this reason, the maxillary second molar should be orthodontically included in the arch form. Occasionally there will be a non-impacted maxillary wisdom tooth that can oppose the mandibular second molar. Articulated dental models with the maxillary segments in their proposed postoperative positions are analyzed to confirm that the posterior maxillomandibular occlusion will be acceptable.

The incorporation of all erupted teeth, including the second molars, within the orthodontic mechanics (especially in the lesser maxillary segment) will facilitate the development of the desired arch form. A lingual attachment on the maxillary first-molar bands allows for the use of a transpalatal arch. This may be useful to support molar anchorage during treatment and to stabilize the surgical result after splint removal. The development of an ideal mandibular arch is usually straightforward. A decompensated

mandibular arch is critical for the effective repositioning of the maxillary segments into the most favorable position at the time of orthognathic surgery.

At the time of the operation, the maxillary segments are secured into a prefabricated acrylic occlusal splint that is then typically left in place for 5 weeks. The patient is educated about the application of elastics and encouraged to remove the elastics intermittently to establish an early range of mandibular opening after surgery. The orthodontist sees the patient within 24 hours of splint removal to replace the maxillary sectional arch wires with a rigid continuous arch wire. Occlusal maintenance and active orthodontic treatment are reinitiated. Close monitoring is essential to maintain the arch form and dental positioning achieved (i.e., horizontal, transverse, and vertical). The placement of a transpalatal appliance (i.e., a wire or a removable palatal plate) may also be useful to maintain the new arch form that is created at the time of operation.

Immediate Presurgical Assessment

Approximately 4 to 6 weeks before the operation, the orthodontist will confirm that the preoperative orthodontic objectives have been met and then place the passive surgical wires. The surgeon takes the final records, which include alginate impressions of the maxillary and mandibular arches, a centric relation bite registration, a face-bow registration, and direct facial measurements. The patient's medical and dental records (e.g., radiographs, consultation reports, facial and occlusal photographs, dental models, special studies) are reviewed. Decisions are finalized with regard to the preferred vector changes (repositioning) of the jaws and the precise linear (millimeter) distances and angles to be accomplished in each jaw for the desired result (see Chapter 12).[2,38,44,45,68,76,94,100,101] Analytic model planning is carried out on the articulated dental casts, and splints are fabricated. The splints assist with the achievement of the precise occlusion and the preferred facial aesthetics that have been decided on preoperatively (see Chapter 13).

Orthognathic Approach for Unilateral Cleft Lip and Palate Deformities

Evolution of Surgical Technique

Historically, the literature warned of possible complications with maxillary osteotomy among patients with UCLP but provided only limited and often confusing descriptions of techniques to guide the orthognathic surgeon in the performance of safe, reliable osteotomies to solve these complex problems.[158]

As with other aspects of orthognathic surgery, Hugo Obwegeser's milestone contributions to cleft skeletal reconstruction are important (see Chapter 2). By the late 1960s, Obwegeser succeeded in advancing a cleft maxilla to the preferred location without the need for a compromised mandibular setback approach. He eventually felt comfortable with cleft maxillary advancements of up to 20 mm. He also realized that the adequate mobilization of the Le Fort I down-fracture was the key step in advancing the maxilla, whether the patient had clefting or not. With experience, the value of simultaneously closing the cleft–dental gap by moving the lesser segment further forward to position the canine in the lateral incisor location was appreciated. This differential segmental repositioning would essentially replace an anterior dental gap for an edentulous space in the posterior maxilla.

Early on, other surgeons without Obwegeser's level of expertise reported complications after advancing the maxilla in patients with UCLP.[113-117,119,120] In 1974, Willmar described the problems that occurred in 17 patients with UCLP who underwent Le Fort I osteotomy. One patient had aseptic necrosis and a partial loss of the lesser segment of the maxilla.[178] In 1974, Georgiade suggested that a camouflage approach with mandibular osteotomies and set-back was preferred to maxillary advancement to avoid complications.[51] Kiehn and others and Des Prez and Kiehn warned of blood-supply problems that might occur with maxillary osteotomies in patients with cleft lip and palate.[30,83] In 1975, Henderson and Jackson reported combining lip-scar revision, anterior fistula closure, and maxillary osteotomy in a one-stage procedure.[69] Their concept was innovative, but they did not specify details of their technique. In 1978, Jackson described the technique of Le Fort I osteotomy in patients with cleft lip and palate and noted that, if a large fistula was present, extensive flap mobilization for closure was required, and the blood supply might be compromised.[77]

Historically, surgeons were leery of completing a Le Fort I down-fracture and full mobilization in patients with UCLP because they feared flap necrosis with a subsequent loss of bone and teeth.[6,7,31-33,52,53,87] In 1980, Tideman and colleagues proposed the segmental palatal osteotomy for patients with cleft lips and palates.[168] This procedure required significant subperiosteal degloving with the potential for compromised flap circulation but without providing the needed direct exposure for full disimpaction. In 1980, Sinn also reported on the simultaneous Le Fort I advancement, oronasal fistula repair, and bone grafting of the alveolar cleft.[155] He stressed the importance of preserving a vertical soft-tissue pedicle, which was similar to that described by Tideman and colleagues. He completed osteotomies through tunnels rather than under direct vision and used a cheek rotation flap for oral-side closure of the labial and palatal oronasal fistulas. With this technique, nonkeratinized buccal mucosa (rather than attached gingiva) was brought into the cleft tooth-bearing region. In 1984, Ward-Booth and colleagues described the results of Le Fort II osteotomy in 13 patients with clefts for the management of midface hypoplasia in an attempt to improve blood supply to the alveolar segments.[175] The residual fistulas were not simultaneously closed, and fixation occurred with direct wires, intermaxillary fixation, and external appliances. In 1985, James and Brook described another variation for the

correction of maxillary hypoplasia in patients with cleft lips and palates via the transection of the hard palate.[78] They raised an extensive palatal flap and used three vertical stab incisions for exposure on the labial aspects of the maxilla. Access was then achieved through subperiosteal tunneling and without direct exposure. Fixation was with intermaxillary fixation and a halo head frame, which was maintained for 10 weeks. A second procedure was required for bone grafting and palatal fistula closure. The authors expressed concern that a more direct down-fracture of the maxilla would result in vascular compromise to the segments. In 1985, Poole and others proposed an additional modification of the Le Fort I osteotomy to be used in patients with cleft palates.[128] With their technique, a partial-thickness palatal flap was elevated, which left the greater palatine vessels in situ and allowed the maxilla to be repositioned anteriorly, without displacement of the soft palate. Poole and colleagues believed that this approach would limit interference with VP function; they also used small vertical incisions on the labial aspect that required tunneling and lacked direct exposure for osteotomies, disimpaction, fistula closure, bone-graft placement, and plate and screw fixation. Fixation in this series was with intermaxillary fixation, direct wires, and a halo craniomaxillofacial head frame.[128]

During the 1980s and the 1990s, Posnick used and refined Obwegeser's original techniques involving Le Fort I osteotomy for the treatment of UCLP deformities.[129-142] A key aspect was the circumvestibular incision, which allowed for direct exposure for dissection, osteotomies, disimpaction, fistula closure, septoplasty, inferior turbinate reduction, pyriform aperture recontouring, bone grafting, and the application of plate and screw fixation (see Fig. 32-5). This was found to be a reliable approach that did not involve the risk of circulation injury to the greater and lesser dento–osseous–musculo–mucosal segments. The visibility provided by the circumvestibular incision made possible the incorporation of routine closure of the cleft–dental gap through differential maxillary segmental repositioning without necrosis of the bone or any loss of teeth. This method also closes the cleft dead space and brings together the labial and palatal flaps without the need for subperiosteal undermining, which allows for the closure of recalcitrant oronasal fistulas without tension and the establishment of the periodontal health of the cleft adjacent teeth. The down-fracture provides ideal exposure for septoplasty; for the reduction of the hypertrophic inferior turbinates; and for the recontouring of the pyriform rims, the floor of the nose, and the anterior nasal spine. The success of this approach, as initially carried out by Obwegeser,[114-117,119,120] was confirmed by Bell's demonstration of the blood supply to these maxillary segments in animal studies.[6-7] The clinical advantages were then further documented by Posnick and colleagues in a consecutive series of UCLP patients.[129-142]

Since the mid 1990s, the literature concerning cleft orthognathic surgery has mostly focused on use of DO techniques to avoid the need for complete intraoperative mobilization of the maxilla in the hopes of improved long-term stability.[166] Although the issue of skeletal stability and dental relapse for precise long-term occlusion is important, it should not overshadow the value of achieving the other planned improvements of the airway and enhanced facial aesthetics.[129-142] Unfortunately, the use of DO techniques has not altered the challenges of cleft jaw surgery, which include the following: 1) a lack of postoperative growth when maxillary advancement is carried out in children; 2) a worsening of VP function in some patients; 3) injury to the teeth and bones if circulation to the segments is not maintained; 4) facial and intraoral sensory loss; 5) suboptimal facial aesthetics when basic principles are not followed; and 6) concern for postoperative skeletal or dental relapse (i.e., residual malocclusion). In addition, DO techniques require a prolonged and labor-intensive postoperative convalescence for the patient and family as compared with the standard approach. Despite these disadvantages, DO does offer hope to the occasional patient with UCLP who also has severe maxillary hypoplasia and anodontia (see Fig. 32-21 and the section about controversies later in this chapter).

Standard Le Fort I Osteotomy

The adolescent or adult CLP patient with a jaw deformity but without a residual fistula and with an intact alveolar ridge of adequate height and volume in the area of the cleft may have been born without alveolar clefting or had a successful graft.[34] For those with adequate alveolar ridge height and volume, a closed palate, and sufficient periodontal support, a standard Le Fort I osteotomy can be performed (see Figs. 32-8, 32-9, and 32-10). A segmental maxillary osteotomy to adjust the arch width, to correct the vertical dimension, or to close the cleft dental gap to avoid the need for a prosthetic lateral incisor may also be necessary in some of these patients (see Chapter 15). Unfortunately, even in the 21st century, a number of adults and adolescents with UCLP with maxillary hypoplasia also present with alveolar defects and oronasal fistulae. For these patients, a modified (two-segment) Le Fort I osteotomy should be considered, as discussed in the next section of this chapter (see Figs. 32-11 through 32-21).[129-142]

Modified Le Fort I Osteotomy (Two Segments)

> *In unilateral cleft cases, the dental gap of the [absent] lateral incisor can be eliminated by advancing the lateral alveolar process so that the canine is positioned next to the central incisor. The canine then subsequently is contoured to match the appearance of the lateral incisor.*[118,119]
>
> **HUGO OBWEGESER**

A maxillary circumvestibular incision is made from one zygomatic buttress to the other without the need to maintain a labial pedicle. Parallel vertical incisions are then made labially in the region of the residual oronasal fistula to

separate the oral and nasal mucosa on each side of the cleft. These incisions are perpendicular to the horizontal vestibular incision and follow the line angles of the teeth adjacent to the cleft (i.e., the canine and the central incisor). The nasal and oral mucosa are carefully incised along the palatal aspect of the residual oronasal fistula. Further separation of the tissue layers is accomplished when dissecting the nasal mucosa free of the bony floor during down-fracture. The complete separation of the oral and nasal layers is necessary for the initial down-fracture and then later for the fistula closure. This is accomplished without degloving the palatal mucosa from the underlying hard palate, because this would compromise the circulation to the maxillary segments.

Before osteotomy, subperiosteal dissection on the anterior surface of the maxilla is completed up to the infraorbital foramina. The anterior nasal spine, the pyriform apertures, and the floor of the nose are also exposed. Dissection continues posteriorly past the maxillary tuberosities to the pterygoid–maxillary suture on each side. After retractors have been put in place, horizontal osteotomies are carried out above the roots of the teeth and into the maxillary sinus through the lateral, anterior, and medial maxillary walls with a reciprocating saw and a long straight blade. The nasal septum is separated from the base of the maxilla with the use of a protected chisel. The pterygoid–maxillary sutures are separated with a curved chisel, and the maxilla is down-fractured. Direct trauma of the palatal mucosa via compressive forces during mobilization should be minimized, because such forces could compromise the vascular supply.

Subperichondrial and subperiosteal dissection of the deviated vomer, the perpendicular plate of the ethmoid, and the quadrangular cartilage is accomplished after the maxilla has been down-fractured. Resection of the deviated and buckled aspects of the septum (i.e., the bone and cartilage) is done with a rongeurs while preserving the structural components of the cartilaginous septum (i.e., the dorsal strut and the caudal strut) that are necessary to prevent a late saddle-nose deformity (see Chapter 15). If the inferior turbinates are enlarged, they are also reduced to improve the airway. The nasal mucosa flaps are sutured for a watertight nasal-side closure. If indicated, the impacted maxillary third molars are removed from above through the maxillary sinus (see Chapter 15).

The down-fractured maxilla may already be in two segments if the bony cleft was unrepaired. If the maxilla is intact but needs correction of the arch form, then it is separated using a reciprocating saw with short straight blade. The approximation of the segments to close the cleft–dental gap can occur after bony spurs are shaved from the alveolus along the distal aspect of the central incisor and the mesial aspect of the canine using a rotary drill with a watermelon bur. Care is taken to avoid penetrating the lamina dura, which would expose the dental root and may result in external root resorption. The maxillary segments are then ligated into a prefabricated acrylic occlusal splint. The segmental repositioning closes the cleft–dental gap, brings the alveolar ridges together, and approximates the labial and palatal mucosal soft tissues for oral-side fistula closure. The differential segmental repositioning approximates the mucosal edges along the palate, so they do not need to be sutured. In fact, to limit invaginations of the oral mucosa, the excision of redundant palatal mucosa is generally required just before the segments are placed in the splint. The placement of the splinted maxilla onto the mandibular dentition should be passive. The extent of maxillary advancement is based on the preferred occlusion and the facial aesthetics determined preoperatively. The ideal vertical dimension is achieved intraoperatively on the basis of the preoperative plan (see Chapter 12). The maxillary osteotomy sites are fixed in place with titanium miniplates and screws at each zygomatic buttress and pyriform rim in accordance with the principles originally described by Luhr.[92] An additional microplate is frequently applied horizontally across the cleft site to stabilize the closure of the cleft–dental gap. The intermaxillary fixation is released, and the occlusion is checked.

The lateral nasal rims, the floor of the nose, and the anterior nasal spine region are recontoured using a rotary drill with a watermelon bur to improve the nasal airway and to enhance nasal aesthetics (see Chapter 15). The dead space associated with the alveolar cleft has already been closed by the differential segmental repositioning. Autogenous iliac cancellous bone graft may be packed along the floor of the nose to raise the ipsilateral sill and across the cleft palate to stabilize the segments. Generally, a crafted iliac corticocancellous bloc graft is placed in between the zygomatic and pyriform fixation plates on each side. Each graft is tightly wedged into the space created by the horizontal advancement and the vertical lengthening (see Chapters 15 and 18). An additional microplate is contoured and secured across the osteotomy, and it also incorporates the graft. With the cleft–dental gap surgically closed, the redundant labial mucosa is excised. Attached gingiva and mucosal edges are approximated without tension and then directly sutured without the need for rotation flaps.

Mandibular and chin osteotomies to correct secondary deformities and facial asymmetries are frequently planned. If so, the osteotomies are completed and secured with plate and screw fixation in standard sequence (see Chapter 15). After the completion of all of the osteotomies and the placement of fixation and grafts, the wounds are closed. The upper and lower teeth are approximated with orthodontic elastics. When maxillary segmental osteotomies are completed, the splint remains wired to the upper teeth postoperatively (see the orthodontic considerations section earlier in this chapter).

Avoiding Pitfalls

Mobilization of the Down-Fractured Cleft Maxilla

Full mobilization of the Le Fort I down-fracture is a critical step in the achievement of accurate intraoperative maxillary

repositioning and then with long-term maintenance. Both pterygoid and nasomaxillary disimpaction forceps are used as needed to achieve full mobilization. Taking the necessary time to slowly complete the disimpaction (i.e., 10 to 15 minutes) is often crucial to achieving the desired results. Gaining confidence—first through observing and assisting an experienced cleft jaw surgeon and then by using one's own hands—is essential to achieving success with the mobilization process.

Horizontal Advancement and Vertical Lengthening of the Cleft Maxilla

The surgeon must often carry out significant horizontal advancement, vertical lengthening, and midline, cant, and occlusal plane correction to enhance facial aesthetics, achieve dental health, and open the airway in a patient with UCLP. The scarring of the palatal soft tissues from previous repairs may be of concern when planning an extensive advancement. A scarred and hypotonic repaired unilateral cleft lip may also caution the surgeon against the vertical lengthening that the midface demands.

In general, to achieve full skeletal correction, all or most of the negative overjet should be managed in the maxilla. The sagitally deficient maxilla in a patient with UCLP will also typically need vertical lengthening. When the maxilla is fully mobilized and repositioned as described previously, stabilization with titanium plates and screws (i.e., a plate at each zygomatic buttress and each pyriform aperture) is performed. The placement of a bloc corticocancellous graft wedged into the dead space between the zygomatic buttress and the pyriform aperture plate on each side is generally necessary (see Chapter 15). Further stabilization across each graft with a titanium plate and screws is also required (see Chapter 15).

Closure of Residual Oronasal Fistula and Alveolar Ridge Management

Ideally, full closure of a residual oronasal fistula and adequate alveolar bone grafting will have been carried out during the mixed dentition. If not, the modified Le Fort I osteotomy in two segments (as described previously) provides the opportunity for complete oronasal fistula closure of the palatal and labial aspects and for the management of skeletal deficiencies without the need for direct alveolar grafting. Many times, grafting and fistula closure will have been carried out during the mixed dentition but without complete correction. A residual fistula may remain on the palatal side; if the dental gap was not closed with the use of orthodontic mechanics (cuspid advancement) after grafting, the volume of bone at the cleft site is likely inadequate for dental implant placement. Unfortunately, when completing a Le Fort I down-fracture without segmental repositioning, any residual palatal fistula cannot be reliably closed, because this would require elevating the palatal flaps and a risk of aseptic necrosis. Direct augmentation of an intact but hypoplastic alveolar ridge at the time of down-fracture is also not practical, because excessive soft-tissue flap elevation around the ridge would be required.

Managing the Nasal Cavity and the Nose

In the patient with UCLP, the inferior turbinates will often be enlarged, asymmetric, and partially blocking the nasal cavity. The reduction of enlarged inferior turbinates will be beneficial for breathing and sinus drainage. The procedure is accomplished through the Le Fort down-fracture (see Chapter 15 and Fig. 32-10).

In the patient with UCLP, the septal bone and cartilage generally show significant deviation and thickening, thus further obstructing the airway. The completion of a submucous resection of the deviated portions of the septum will be helpful to open the airway. The preservation of caudal and dorsal cartilaginous struts will prevent a saddle deformity; this is accomplished through the Le Fort down-fracture (see Chapter 15 and Fig. 32-10).

In the patient with UCLP, the pyriform rims are generally constricted and asymmetric. The nasal floor is uneven, and the anterior nasal spine is deviated. After Le Fort down-fracture, the recontouring of the pyriform rims and the nasal floor and spine using a rotary drill with a watermelon bur is helpful to open the airway and improve nasal aesthetics (see Chapter 15 and Fig. 32-10).

Attempts to "control" the nasal soft-tissue envelope with suturing techniques (e.g., the alar cinch stitch) after Le Fort I osteotomy are often suggested. In my experience, manipulating the nasal soft tissues with suturing techniques after Le Fort I may be counterproductive to both the airway and the facial aesthetics. We anticipate that the nasal soft tissues will be redraped over the repositioned maxilla and the recontoured pyriform rims, nasal floor, and nasal spine for an overall improvement in aesthetics. A definitive rhinoplasty to fully correct the UCL nasal deformities is often beneficial; this is best postponed until 6 to 12 months after jaw reconstruction (see Chapter 38).

Immediately after surgery, the nasal cavity is not packed, and the septum is not stented. Coagulated blood will partially block nasal breathing. The clots and scab are expected to dislodge and be self-eliminating after the underlying mucosa is initially healed (i.e., 5 to 7 days after surgery). The use of saline nasal sprays and the institution of sinus precautions are helpful during this time (see Chapter 11).

Management of the Mandibular Deformity

In the individual with UCLP, the mandible is often secondarily deformed. In a previously published study, 70% of the patients with UCLP had secondarily deformed mandibles to the extent that sagittal split ramus osteotomies were beneficial to improve facial symmetry and proportions.[141] The mandibular repositioning is not carried out in an attempt to avoid maxillary advancement but rather to improve overall facial morphology (see Chapter 15).

Management of the Chin Deformity

In the patient with UCLP with maxillary hypoplasia, the chin is often secondarily deformed, with increased vertical length and a flat pogonion. An intraoral oblique inferior border osteotomy is carried out with repositioning and reshaping of the distal chin to accomplish the preferred morphology (see Chapters 15 and 37).

Clinical Management after Initial Surgical Healing

Managing the details of the in-hospital and at-home convalescence during the initial healing of the orthognathic patient are essential for a successful outcome (see Chapter 11). Cephalometric and dental radiographs and facial and occlusal photographs are obtained at standard postoperative intervals to document patient healing. The orthodontist sees the patient within 24 hours of splint removal (approximately 5 weeks after surgery) and replaces the maxillary sectional arch wires with a rigid continuous arch wire. The maxillary teeth are ligated together to maintain the surgical dental-gap closure, the horizontal advancement, and the transverse expansion. Active orthodontic maintenance and finishing are started. The use of a transpalatal appliance (i.e., a wire or a palatal plate) may also be used to stabilize the new arch form. Close monitoring by an orthodontist for skeletal and dental shifts during the first 6 months after surgery is essential.

Speech can be objectively reassessed 3 to 6 months after surgery. We prefer to do so with the use of nasoendoscopic instrumentation. Definitive cleft soft-tissue procedures (e.g., cleft rhinoplasty, lip scar revision, pharyngeal flap or flap revision) can be carried out as early as 6 months after orthognathic surgery. After the orthodontic appliances are removed, any planned definitive dental restorative work can be finalized.

Orthognathic Surgery for Unilateral Cleft Lip and Palate: Review of Study

Patients and Methods

Posnick and Tompson prospectively assessed the cleft deformity and clinical results of 66 consecutive adolescents and young adults (age range, 15 to 25 years; mean, 18 years) with UCLP who underwent orthognathic surgery by one surgeon (Posnick) with the use of a single surgical protocol during a 6-year time period.[141] All patients underwent perioperative orthodontic treatment and were judged to be skeletally mature at the time of jaw surgery. The clinical follow-up period after maxillary advancement ranged from 1 to 7 years (mean, 40 months). The countries of origin of the patients varied (e.g., Canada, United States, Eastern Europe, Southeast Asia), as did their races (e.g., Caucasian, Asian, African). These patients had their cleft lips and palates repaired by many different surgeons who were using a variety of protocols. The number and extent of previous revisions of the lip, nose, and palate varied greatly (range, 1 to 9 procedures). Many patients had undergone multiple attempts at closure of the residual oronasal fistula and at the reconstruction of the alveolar clefts with bone graft. Seven of the 66 patients with UCLP had previously undergone orthognathic surgery by another surgeon; all seven had residual maxillary hypoplasia, a recalcitrant oronasal fistula, and a cleft–dental gap.

The basic orthognathic procedure carried out by Posnick included a modified Le Fort I osteotomy in two segments (n = 66). Twenty-three of these patients also require simultaneous sagittal split ramus osteotomies to correct facial asymmetry and disproportion. Thirty-five of the 66 patients (53%) underwent osseous genioplasty (vertical reduction and horizontal advancement) to improve their profile aesthetics and lip position.

The 66 adolescents with UCLP had multiple residual deformities, and all but one had residual oronasal fistulas of varying sizes. Sixty-four of the 66 patients (97%) presented with negative overjet at the central incisors. Sixty of the 66 patients (91%) had a lateral (posterior) crossbite of the lesser segment and a maxillary dental midline that was not coincident with the facial midline. An Angle Class III malocclusion was present on the cleft side in 64 of 66 patients. In 60 of the 66 patients (91%), a congenitally absent or structurally inadequate lateral incisor was present at the cleft site. Simultaneous differential repositioning of the maxillary segments was planned for all 66 patients. In 57 of the 60 patients who presented with a cleft–dental gap, surgical closure through segmental repositioning also was planned. Despite the successful preoperative orthodontic cleft–dental gap closure in six patients, surgical arch width and coordination problems remained and required segmental repositioning.

Results

Sixty-one of the 66 patients (92%) underwent successful simultaneous oronasal fistula closure. In the five patients with residual fistulas, definitive closure with standard mucogingival and palatal flaps as a secondary procedure was possible and did not require bone grafting. Surgical cleft–dental gap closure was achieved and maintained in all but 3 of the 57 patients in whom it was attempted. In these patients, the dental gap closure was achieved initially; however, over the subsequent 12 months, the teeth in the lesser segment shifted position. The dental gap opened even though the fistula remained closed, and skeletal continuity across the cleft remained intact.

Nine patients required fixed (prosthetic) bridgework, either to complete the closure of the cleft–dental gap or to achieve other aspects of dental rehabilitation. A bridge was required in three patients in whom a dental gap was intentionally left open and in three others when the space reopened. The techniques of porcelain-veneer finish,

composite resin buildups, and tooth sculpting were used to resurface incisor teeth in three other patients as a result of chronic tooth decay and enamel dysplasia.

In all patients, keratinized mucosa was successfully maintained along the labial surface of the cleft-adjacent teeth (n = 132 teeth). Preoperative gingival recession along the distal aspect of the central incisor as a result of longstanding limited alveolar support could not be improved at the time of the orthognathic surgery. Five of the 132 cleft-adjacent teeth required root canal therapy, and five teeth were noted to have further gingival recession after the completion of orthodontic treatment.

The long-term maintenance of overjet was measured directly from the late (>1 year) postoperative lateral cephalometric radiograph; all but two patients (i.e., 64 out of 66) maintained a positive overjet. The long-term maintenance of overbite was also measured directly from the late postoperative lateral cephalometric radiograph; 60 of 66 patients (91%) maintained a positive overbite; 4 patient shifted to a neutral overbite; and 2 patients relapsed into a negative overbite.

Complications were few and generally not serious. One patient who had also undergone septoplasty and inferior turbinate reduction was returned to the operating room for nasal packing to manage epistaxis on postoperative day 10. In another patient, the maxilla was repositioned a second time to reduce the vertical height (gingival show) for improved facial aesthetics on postoperative day 3. No loss of segmental bone or teeth occurred as a result of aseptic necrosis, infection, or for any other reason.

Skeletal Stability after Modified Le Fort I for Unilateral Cleft Lip and Palate Deformity: Review of Study

In general, published studies of long-term skeletal stability after cleft–orthognathic surgery tend to group populations that should be considered separately (e.g., BCLP, UCLP, isolate cleft palate); they have an inadequate follow-up period (e.g., <1 year) or too small of a sample for statistically significant results; or they only provide information about cephalometric measured length and angles rather than evaluate clinically relevant parameters (e.g., maintenance of overjet).

Patients and Methods

Posnick and colleagues reviewed medical records and cephalometric radiographs and completed current surgical and orthodontic clinical examination of all patients (n = 45) with UCLP who had undergone Le Fort I osteotomy by a single surgeon (Posnick) during a 3-year period.[139] The following information was noted: all previous maxillofacial procedures, details of the orthognathic procedures, osteotomy stabilization techniques used, the presence of a pharyngoplasty, the extent of bone grafting, the segmentalization of the Le Fort I osteotomy, perioperative orthodontics, the age at surgery, the age at final follow up, the amount of overjet and overbite at the 1 year or more postoperative visit, and perioperative morbidity.

For all patients, the prospective protocol required a lateral cephalogram preoperatively, immediately (i.e., 3 to 7 days after surgery), at 6 to 8 weeks, and at 1 year after surgery. At the time of the clinical review, patients were excluded from the study if one or more interval cephalograms were not available (n = 7) or if less than 3 mm of horizontal advancement was required to correct their skeletal deficiency (n = 3).

The serial radiographs for each patient were analyzed with a modified version of the method described by Bachmayer and colleagues.[5,6] On each preoperative tracing, the horizontal and vertical coordinates that represented the patient's natural head position were constructed so that they passed through the sella. These reference lines were transferred and became the x-y grid template onto which all of the postoperative maxillary positional changes could be traced and measured. The end result was a Cartesian coordinate system that illustrated the horizontal and vertical directional changes of the maxilla at intervals after surgery. The measurements of the differences in the position of the maxilla at different postoperative points were taken from the grids and were calculated to within 0.5 mm. In addition, the incisor overjet and overbite measurements from the 1-year (or more) postoperative cephalogram were documented and compared with the measurements taken at the final (1 year or more postoperative) clinical assessment. Differences between groups (e.g., pharyngeal flap in place) were assessed via Student's *t*-test. Any association between the magnitude of surgical change and the degree of relapse was examined with the Pearson correlation coefficient (*r*) and the least-squares linear regression analysis. Correlations were considered significant when the *P* value was less than .05.

Results

During this study period, 45 skeletally mature patients with UCLP patients underwent Le Fort I maxillary advancement. None were lost to follow up and the final clinical follow-up examination ranged from 1.5 to 4.5 years (mean, 2.5 years) from the time of the surgical procedure and the close of the study. Seven patients missed one of their longitudinal cephalometric records, and three required less than 3 mm of horizontal advancement to correct their maxillary deformity. The 10 excluded patients were reviewed and were not clinically different from the other 35, varying only for the reasons outlined. All patients in the study were judged to be skeletally mature at the time of operation on the basis of the assessment of either a carpal (wrist) radiograph or at least two static serial cephalometric radiographs taken at 6-month intervals. For the 35 patients who were included in the study, the age at operation ranged from 14 to 25 years (mean, 18 years).

All 35 study patients underwent modified Le Fort I osteotomies (two segments) with varying degrees of horizontal advancement, transverse arch widening, and vertical change. Eleven of the 35 patients also underwent sagittal split ramus osteotomies of the mandible to correct asymmetries and secondary deformities; 22 had vertical reduction genioplasty with or without chin advancement to improve their profile aesthetics. In 13 of 35 patients, a pharyngoplasty was in place at the time of the maxillary osteotomy. None required takedown or modification of the flap to achieve passive intraoperative maxillary placement. All 35 patients underwent perioperative orthodontic treatment that was coordinated with their surgical procedure.

No statistically significant differences were seen in the initial vertical or horizontal surgical changes and the postoperative maintenance (relapse) between patients who had maxillary surgery alone or those who had surgery in both jaws and those who had a pharyngoplasty in place at the time of their Le Fort I osteotomy ($P < .05$). Therefore, these patients were considered a homogeneous group for further analysis. The mean horizontal advancement at the incisors achieved for the group was 6.9 mm, with 5.3 mm maintained 1 year later. In 11 of the 35 patients, the relapse was less than 1.0 mm. The amount of horizontal relapse did not correlate significantly with the amount of maxillary advancement ($r = .31$).

In the 13 patients with a pharyngoplasty in place at the time of the Le Fort I osteotomy, the mean effective horizontal advancement was 8.2 mm immediately after the operation and 6.5 mm 1 year later. Interestingly, the 22 patients without a pharyngoplasty in place required less horizontal advancement, with a range of 6.4 mm and 4.9 mm maintained at 1 year. The mean vertical change of the maxilla was 2.1 mm initially after the operation and 1.7 mm 1 year later. In 12 of the 35 patients, no vertical change was necessary; in the remaining patients, vertical directional change was necessary and achieved. Analysis indicated that vertical relapse did not correlate significantly with the magnitude of change that occurred at the time of surgery ($r = .41$). The authors also measured the overjet and overbite directly from the cephalometric radiographs at the 1-year postoperative interval in each patient. A positive overjet was maintained in all patients, whereas a positive overbite was maintained in 86% (30 of 35 patients). This data confirms that, with the combination of orthodontics and orthognathic surgery, a functional long-term occlusion was achieved in most of the patients with UCLP.

Controversies and Unresolved Issues

Staging of Maxillary Reconstruction

The described modified Le Fort I segmental osteotomies as a method of managing end-stage oronasal fistulas, alveolar defects, and cleft–dental gaps in patients with UCLP who have maxillary hypoplasia is not intended to replace standard techniques and the accepted sequencing of treatment. We always prefer secondary bone grafting during the mixed dentition typically with orthodontic closure of the cleft dental gap. However, the method described does offer an alternative approach when the opportunity for grafting during the mixed dentition (i.e., before the eruption of the permanent canine) is lost and a jaw deformity also exists. Published studies from major cleft centers in the United Kingdom, Scotland, and Canada confirm that, despite best efforts, a number of patients in the mixed dentition will not arrive for treatment, and a percentage of those who do will undergo unsuccessful grafting.[39,103,108,177] A two-stage approach to the adolescent or adult with maxillary hypoplasia, residual alveolar clefts, oronasal fistulas, a cleft–dental gap, and nasal obstruction is not cost- or time-effective and, in my experience, the potential overall morbidity is increased. It is in these patients with UCLP that the modified Le Fort I osteotomy offers a reasonable opportunity for the resolution of residual end-stage problems (e.g., maxillary hypoplasia, alveolar defect, residual fistulas, cleft–dental gap, nasal obstruction) in a safe and effective way.

In the patient with UCLP, there are several options for the management of a cleft–dental gap.* From both facial aesthetic and dental health perspectives, the long-term use of a removable partial denture is always a second choice. Fixed bridgework is a viable alternative, but this requires the partial destruction of adjacent normal teeth, it may look artificial, it requires replacement at intervals throughout the patient's life, and it demands ongoing meticulous oral hygiene (i.e., high-maintenance dentition). Placement of a single-tooth osseous integrated implant is an attractive alternative, but the implant's aesthetic success is dependent on adequate bone height, width, and volume and sufficient attached gingiva.[62,93,122,124,146,165,166,172,174,185] This is not routinely established at the cleft site, even after bone and gingival grafting. In addition, it requires staged surgical procedures, and it also produces a high-maintenance dentition. Coordinated comprehensive periodontal and prosthetic rehabilitation is required, and even then failure to provide a natural-looking smile may occur. In a published study conducted at The Hospital for Sick Children in Toronto, only 10% of complete UCLP lateral incisor dental gaps were managed with a dental implant and crown.[17] Other dental refinements for a patient's dysmorphic and often hypoplastic and decayed anterior maxillary teeth include porcelain-veneer buildups, composite bonding, sculpting of the teeth, and bleaching techniques. Each of these refinements may improve the patient's function, smile aesthetics, and self-esteem.

A major advantage of the described modified Le Fort I (segmental) osteotomies in the patient with UCLP is its ability to simultaneously close the cleft dead space, the residual oronasal fistulas, and the alveolar defect and to stabilize the dentoalveolar segments. The study by Posnick

*References 1, 10, 17, 58, 62, 64, 74, 93, 112, 122, 124, 145, 146, 159, 161, 163, 165, 166, 172, 174, 176, 185

and colleagues documents the improved long-term periodontal health achieved in the cleft dentoalveolar regions when this technique is used.[141] The long-term benefits to the patient of the resulting low-maintenance dentition cannot be over stated. Another advantage of this approach occurs when the lesser segment is advanced to attain this goal. By doing so, a relative arch-width expansion is gained at the mandibular molar and the premolar region without the actual need for a lateral shift of the whole segment. This limits any arch-width relapse tendencies.

Velopharyngeal Function after Le Fort I Advancement

Uncertainties about VP function and the management of an in-place pharyngeal flap should no longer be limiting factors when orthognathic surgery is necessary in a patient with a cleft. A nasoendoscopic guided examination by a speech pathologist and a surgeon who are familiar with cleft anatomy can reasonably predict current and expected VP function in a patient who is scheduled for a Le Fort I osteotomy (see Chapter 8). When postoperative VP deterioration is anticipated, the patient and family are counseled about the sequencing of treatment. Clinical studies have now documented that VP function will deteriorate in a similar fashion when either DO or standard Le Fort I osteotomy techniques are used.[19,20,57,60,79,86] Despite the frequent need for significant maxillary advancement to normalize the skeleton and the facial aesthetics in patients with UCLP, I have not had to transect an in-place pharyngeal flap to achieve maxillary mobilization. Our research and that of others confirms that a pharyngeal flap in place at the time of Le Fort I osteotomy does not increase complications nor does it result in a higher incidence of relapse.[141] The definitive reassessment of VP function after cleft Le Fort I advancement can be carried out 3 months after surgery. A primary or revision pharyngeal flap can be safely carried out within 6 months after surgery in conjunction with cleft rhinoplasty or labial revision, if indicated.

Mixed Dentition Le Fort I Osteotomy

By the mid 1980s, research clarified that, if jaw surgery is undertaken in the growing patient with a cleft palate, another procedure to advance the maxilla will likely be required when skeletal maturity is reached.[181-184] More recently, several investigators again tested this theory by proceeding with mixed-dentition Le Fort I procedures using DO techniques. All research to date indicates that the Le Fort I advancement carried out during the mixed dentition in the patient with clefting—whether with standard or DO techniques—results in no significant further horizontal growth.[21,26,40,41,59,61,75,126] As the mandible continues to grow, an Angle Class III malocclusion will occur with the need for either additional Le Fort I advancement or mandibular set-back.

Skeletal Relapse after Le Fort I Osteotomy in Patients with Clefting

There are more than 100 published articles reviewing skeletal stability and relapse in patients with clefting who have undergone Le Fort I advancement with the use of either standard osteotomy or DO techniques.* Proponents of DO techniques frequently state that, when more than 10 mm of horizontal maxillary advancement are required, the use of standard osteotomies with plate and screw fixation and bone grafting may lead to a greater degree of relapse. However, these studies do not report convincing data that demonstrate significant differences in relapse patterns between the two techniques. To give this situation some perspective, it should be noted that only 5% of patients with clefting who are undergoing Le Fort I advancement will require more than 10 mm of horizontal advancement at the incisors. All clinicians agree that this subgroup of patients is the most challenging to treat, but the reasons for this go beyond the degree of horizontal maxillary deficiency. These patients are also likely to present with multiple residual end-stage deformities (see the section about residual skeletal deformities earlier in this chapter), multiple missing teeth, and previously failed surgical procedures.

Aksu and colleagues documented a horizontal maxillary (skeletal) relapse of 22% in patients with cleft lips and palates after Le Fort I osteotomy with the use of DO techniques.[4] He and colleagues reported their results for adolescent patients with repaired cleft lips and palates and maxillary hypoplasia who then underwent Le Fort I advancement with the use of an external DO device.[65] The patients (n = 17) were treated at one center between 2000 and 2006, and they had at least 1 year of follow up and a full set of records. DO treatment was started on day 5 (1 mm per day) and continued until a Class II occlusion (i.e., overcorrection) was achieved. Consolidation time ranged from 4 to 12 weeks, and this was followed by several more months of face mask therapy. The first four patients (two UCLP and two BCLP) who were treated developed fibrous non-union, and all four required reoperation and rigid (i.e., titanium plate and screw) fixation to achieve union. The authors then extended the consolidation period to a minimum of 12 weeks for the remaining patients (n = 13); all of these patients achieved bony union. In the group that achieved satisfactory bony union (13 out of 17 patients; 76%), the mean horizontal relapse was 11.9%, with 5 of 13 patients (38%) developing no better than end-to-end occlusion. Another orthognathic procedure was necessary in 5 of the 13 patients (38%) who initially achieved bony union to obtain a satisfactory occlusion. Overall, 9 out of 17 patients (53%) required two orthognathic procedures. In 2011, **Chen and colleagues** reported a 30.7% incidence of horizontal skeletal relapse 1 year after Le Fort I osteotomy in

*References 3, 11-13, 18, 21-24, 27, 35-37, 40, 41, 43, 46, 50, 55, 59, 61, 65-67, 71-73, 81, 107, 127, 129-142, 149, 160, 162, 168, 173, 179

patients with clefts who were treated with DO techniques (i.e., the RED device). This was in a consecutive series of patients who presented with Class III malocclusion as a result of cleft maxillary hypoplasia and who agreed to a combined orthodontic and surgical approach.[21] **Posnick and colleagues** documented the degree of horizontal relapse and overall occlusal success when using the modified Le Fort I technique as described in this chapter for patients with clefts. They measured horizontal change, stability, and information concerning the maintenance of overjet and overbite from 1-year or more postoperative cephalometric radiographs and clinical examinations.[141] The results were reported in accordance with cleft type: patients with UCLP had 6.9 mm mean advancement with 5.3 mm maintained; 94% of patients with BCLP maintained positive overjet for the long term; and patients with isolate cleft palate had 6.1 mm mean advancement with 5.1 mm maintained. Interestingly, the degree of relapse that was documented was less than that generally reported by clinicians who use DO approaches (see earlier).

Standard Approach versus Distraction Osteogenesis Approach to Le Fort I Advancement

As Obwegeser stated in the 1960s and as was confirmed by Precious and colleagues, "relapse in cleft patients [after Le Fort I advancement] may well be more related to failure to adequately mobilize the maxilla and free it of abnormal soft tissue attachments than anything inherent in the osteotomy or the specific [cleft] diagnosis."[113-117,119,120]

I agree with Obwegeser when he stated the following: "Today, many surgeons will resort to the use of distraction devices to gradually advance the cleft maxilla. Although in some circumstances this may be appropriate, it should be remembered that most cleft patients can be treated efficiently, even when requiring significant advancement with the classic Le Fort I type procedure."[119]

Standard thinking is for the surgeon to commit to an approach (DO versus standard technique) for Le Fort I advancement before he or she arrives in the operating room. The surgeon then sticks to the plan, no matter what happens intraoperatively. On the basis of a review of the literature and almost three decades of personal experience as a cleft jaw surgeon, I make the following observations and recommendations in this area.

Observations About the Distraction Osteogenesis Approach

- DO techniques are always the patient's second choice when compared with the standard approach of Le Fort I osteotomy with rigid (plate and screw) internal fixation. The length of convalescence after surgery involving DO is longer; it will include at least 3 months of limited diet and physical activities, and it is generally followed by several additional months of face mask therapy. The DO device is also awkward and socially embarrassing, as it typically blocks the patient's visual fields (e.g., the RED, BLUE, or GREEN external DO devices). Furthermore, there is no overall reduction in the potential for perioperative complications with DO techniques.
- If the cleft maxilla is adequately down-fractured, mobilized, and stabilized with interpositional bone grafts and rigid plate and screw fixation, it has a high probability of healing as planned with a predictable and less extensive convalescence than would be necessary with DO.
- An experienced orthognathic surgeon will be more confident with his or her ability to down-fracture and fully mobilize the cleft maxilla than a less experienced surgeon. Therefore, the less experienced surgeon will more likely select DO techniques to avoid the personal stress of the intraoperative maxillary mobilization process.
- Even for the experienced cleft orthognathic surgeon, there will be the occasional patient in whom the extent of maxillary hypoplasia and associated deformities (e.g., missing teeth, lack of alveolar bone) will lead him or her to choose a DO technique. Despite its protracted healing requirements and its limited ability to correct all of the cleft deformities, the DO device's gradual stretching ability can mobilize even the most recalcitrant maxilla (see Fig. 32-21).

Recommendations for the Distraction Osteogenesis Approach

For most cleft patients with maxillary hypoplasia, reserving DO techniques to serve as a "bail out" when the down-fractured maxilla cannot be adequately mobilized is the approach that I recommend. The rare patient and family at risk can be informed of this contingency plan in advance. This approach allows the surgeon to have flexibility in the operating room to make the right decision at the right time for the patient in need to achieve the most efficient convalescence and the most favorable long-term objectives.

Conclusions

There are now convincing clinical studies that document a high prevalence of jaw deformities in mature patients with repaired UCLP. The methods described to manage the adolescent and adult with UCLP who presents with jaw deformities, malocclusion, a residual oronasal fistula, bony defects, a cleft–dental gap, nasal obstruction, sleep apnea, and aesthetic needs are generally safe and reliable when performed by a dedicated orthognathic surgeon and team. Successful cleft orthognathic and intranasal procedures provide a stable foundation on which final soft-tissue lip and nose reconstruction may be carried out.

- Controversies and Unresolved Issues
- Conclusions

The reconstruction of bilateral cleft lip and palate is inextricably connected with orthodontic care and skeletal surgery. The successful management of these individuals is likely to present a formidable clinical challenge for the orthognathic surgeon, the orthodontist, and the dental team.

Facial Growth Implications of Cleft Palate Repair in the Infant with Bilateral Cleft Lip and Palate Deformity

Ross confirmed that individuals who are born with cleft lip and palate have intrinsic deficiencies in the midfacial skeleton that are made significantly worse by operations.[118] Mulliken and colleagues from Boston Children's Hospital found that 76.5% of teenagers with repaired bilateral cleft lip palate (BCLP) required maxillary advancement.[43] They showed that the need for orthognathic surgery is dependent on the severity of the cleft type as well as the number and extent of previous operative procedures. Results from The Hospital for Sick Children in Toronto, Canada, showed that 65.1% of their patients with BCLP required or underwent orthognathic surgery, whereas 70% of children with BCLP who were referred to their team some time after cleft lip repair were found to require orthognathic surgery.[23] David and colleagues from the cleft craniofacial unit in Adelaide, Australia, followed a consecutive group of patients with BCLP from birth to maturity and determined the need for orthognathic surgery.[24] Each patient was followed according to treatment protocol and then at 18 years of age assessed for dentofacial deformity. A skeletal Class III malocclusion that required orthognathic correction was present in 17 of the 19 patients (89.5%), whereas the remaining 2 patients were found to have a malocclusion that was manageable with orthodontics alone. Fourteen underwent orthognathic surgery, and the remaining three declined the offer for correction.

Saperstein and colleagues discussed facial growth in children with complete clefting of the primary palate (i.e., the lip through the incisal foramen) but with an intact secondary palate (i.e., the incisal foramen through the uvula).[120] This was a retrospective, cross-sectional analysis of nonsyndromal patients with bilateral complete clefting of the

primary palate (n = 7) as compared with those with bilateral complete clefting of both the primary and secondary palates (n = 27). Angular and linear measurements of the midfacial region were made on lateral cephalograms. The research documented that individuals with a bilateral cleft of the primary palate who underwent lip repair during infancy most frequently have a normal or even slightly forward maxillary position as compared with age-matched controls. This was in contrast with children with a bilateral cleft of both the primary and secondary palates who underwent lip repair followed by palate repair before they were 1 year old, who demonstrated a high incidence of maxillary deficiency. The study clarified that cleft palate repair carried out before the patient is 1 year old—and not the cleft lip repair itself—is responsible for the high incidence of midface hypoplasia.

It is now clear that orthognathic surgery is a necessary component of the treatment of a majority of individuals who are born with BCLP. Unfortunately, the necessary jaw reconstruction is often considered "too risky" and therefore postponed, delayed, ignored, or refused. If so, the patient is likely to be treated with orthodontic and prosthetic camouflage techniques. Adding further difficulty to successful rehabilitation is controversy about the indications and confusion regarding the exact techniques, timing, and extent of surgery needed to achieve reliable and predictable results. The occlusal, speech, upper airway, and aesthetic objectives in the adolescent patient with BCLP must first be clarified. A surgical, orthodontic, and dental treatment plan can then be coordinated to achieve improved head and neck function, facial enhancement, and dental rehabilitation.

Coordinated Team Approach

The care of the patient with BCLP is best delivered by an integrated group of dental and medical specialists who evaluate and then provide coordinated definitive treatment.[8,77,92] It is no longer acceptable for individual surgeons, orthodontists, restorative dentists, speech pathologists, and otolaryngologists to carry out extended treatment without considering all aspects of the patient's care and communicating effectively with the patient, the family, and the collaborating clinicians. The Eurocleft study found no association between high-intensity treatments and favorable results. In other words, the more operations and years of orthodontic appliances (i.e., heavy burden of care), the worse the outcome.[79]

Treatment Protocol

Adolescents and adults with BCLP who also have jaw deformities should be seen at a minimum by an orthodontist, an orthognathic surgeon, an otolaryngologist, and a speech pathologist. Additional consultations with other dental (e.g. a prosthodontist, a pediatric or general dentist, a periodontist) and medical (e.g., sleep specialist, medical geneticist) specialists are obtained, if necessary. For the initial evaluation and eventual treatment of the cleft dentofacial deformity, records and tests should include the following: medical-quality photographs with views of the face and the occlusion; cephalometric and dental radiographs; dental models; direct facial measurements; speech assessment; and thorough evaluation of the upper airway.

In addition to performing lip, palate, and velopharyngeal (VP) repairs, the primary cleft surgeon generally plays a role in advising the patient and the family about the patient's further care. If the cleft surgeon is not trained in skeletal procedures, then a timely and seamless transition to the maxillofacial surgeon who will continue on with the patients' reconstruction should go forward. The cleft jaw surgeon should have a fundamental understanding of the patient's dental, speech, upper airway, and aesthetic needs. The surgeon should request consultation with appropriate specialists, evaluate the clinical information, and be prepared to go forward with coordinated and timely up-to-date orthognathic procedures.

The orthodontist provides interceptive treatment during the mixed dentition in coordination with bone grafting; and carries out definitive orthodontics in conjunction with orthognathic surgery, when indicated. From the mixed-dentition phase, the orthodontist should recognize the patient with BCLP who will likely be in need of orthognathic surgery.[20,21,25,36,52,53,64,80,90,114,117,121,132,145] Instituting extensive camouflage (dental compensatory) treatment is likely to jeopardize periodontal health and lead to late dental relapse of the occlusion. Proceeding with a compromised orthodontic (camouflage) approach should only be entered into with full disclosure to the family and other treating clinicians.

Before orthognathic surgery, a speech pathologist performs an evaluation to characterize VP function and to identify articulation errors that result from the cleft palate, the jaw deformity, and the dental malocclusion (see Chapter 8). Such evaluation is important, because VP function may deteriorate after maxillary advancement. A nasoendoscopic guided speech assessment is preferred to obtain maximum objective data. VP closure that is adequate before surgery may become borderline afterward, and VP closure that is borderline may become inadequate. The successful orthodontic, surgical, and dental correction of crossbites, open bite, cleft–dental gaps, negative overjet, and residual oronasal fistula represents the most effective way to correct the identified articulation distortions (see Chapter 8).

A thorough evaluation of the upper airway is conducted to assess for any areas of obstruction (see Chapter 10). A formal sleep study (polysomnogram) is completed if there is a suspicion of obstructive sleep apnea (see Chapter 26). If indicated, simultaneous intranasal procedures to open the airway should be carried out at the time of orthognathic surgery (see Chapters 10 and 15).

Discussions with the treating medical and dental consultants as well as the patient and his or her family clarify the need for and the extent of orthognathic procedures (e.g., Le Fort I osteotomy, sagittal ramus osteotomies, osseous

genioplasty) and intranasal procedures (e.g., septoplasty, inferior turbinate reduction, recontouring of the nasal floor and rims). The overall plan for speech, jaw, upper airway, and dental rehabilitation and the enhancement of facial aesthetics is agreed to before the initiation of treatment.

Timing of Orthognathic Surgery

Correction of the cleft jaw deformity is best carried out with a consideration of skeletal maturity and before the patient finishes high school.[66,69] Maxillofacial growth is generally complete between the ages of 14 and 16 years in girls and the ages of 16 and 18 years in boys. However, skeletal growth is variable, and it may be further clarified by an analysis of sequential cephalometric radiographs taken at intervals (see Chapter 17). Patient and family preferences for the timing of reconstruction on the basis of the patient's psychosocial and functional needs (i.e., speech, swallowing, chewing, and breathing) should also be taken into account.

As early as 1986, investigators showed that, if Le Fort I advancement is completed during the mixed dentition in a patient with a cleft palate, then another orthognathic procedure will be necessary after skeletal maturity is reached.[140-143] All research to date indicates that a Le Fort I osteotomy carried out at an early age, with the use of either standard or distraction osteogenesis (DO) techniques, results in no further horizontal maxillary growth.[16,34,35,46,48,59,95]

Residual Deformities in the Adolescent with Bilateral Cleft Lip and Palate

The adolescent patient with BCLP often has several residual deformities that can be challenging to manage. The central deformity is maxillary hypoplasia, which is often combined with residual oronasal fistula, bone defects, intranasal obstruction, soft-tissue scarring, and occasionally VP dysfunction (Figs. 33-1 through 33-17). In addition, the maxillary lateral incisors are usually congenitally absent or hypoplastic (93% of the time), and the patients often have cleft–dental gaps.[13] Secondary deformities of the nose, the mandible, and the chin region are also common. The prevalence of these residual deformities in mature patients with BCLP varies widely, depending on the treating clinician's philosophy, available expertise, the individual's intrinsic biologic growth potential, and patient and family interests. Published clinical surveys indicate that, despite a cleft team's best efforts, a significant number of children with BCLP will not make themselves available for mixed-dentition grafting (i.e., before the eruption of the maxillary canines).[33,137] In addition, a percentage of those who do will undergo unsuccessful grafting procedures and require other means of reconstruction and dental rehabilitation. For all of these reasons, a subgroup of individuals with BCLP continues to present at or after adolescence with multiple cleft-related challenges that may include the following:

1. *Maxillary hypoplasia.* The anterior maxilla may be either vertically long, which results in a gummy smile, or vertically short, which leaves an edentulous appearance. Horizontal deficiency (negative overjet) with a flat midface and an Angle class III malocclusion is also part of the usual presentation. The arch width of the lateral segments is frequently deficient (or at least pseudodeficient as a result of the negative overjet), with posterior crossbites. The dental midline may be shifted off of the facial midline, and the maxillary lateral segments may be canted. For the individual who was not effectively grafted during the mixed dentition, the two lateral segments and the premaxillary segments are separate components of the upper jaw. In general, each segment will vary with regard to its degree of vertical and horizontal dysplasia. These patients are best treated via the differential repositioning of each of the three segments to achieve a satisfactory arch form, occlusion, and facial appearance.
2. *Residual oronasal fistula.* Although the preference is to complete fistula closure and bone grafting during the mixed dentition (i.e., before the eruption of the canine at each cleft site), some patients with BCLP will have residual labial and palatal fistulas, with leakage of fluid through the nose while drinking and air leakage while speaking. Previous attempts at fistula closure may have failed as a result of inadequate available (palatal) soft tissue for wound closure in the incisal foramen region.
3. *Cleft–dental gaps.* Approximately 93% of the time, useful lateral incisors are absent or inadequate at each cleft site. A rudimentary lateral incisor or supernumerary tooth may be impacted or adjacent to each cleft; if so, they are of no functional value. If hypoplastic lateral incisors do erupt in the posterior or premaxillary segments, they rarely have the root support needed for long-term function. The result is often a dental gap at the cleft site between the central incisor and the canine on each side. If bone grafting and fistula closure during the mixed dentition were successfully carried out, then canine eruption followed by orthodontic closure of the cleft dental gaps will have likely been undertaken.
4. *Residual bony defects.* In the patient with BCLP who has not had successful or adequate bone grafting during the mixed dentition, significant residual defects through the alveolus, the floor of the nose, and the palate remain. A lack of continuity across the cleft alveolar ridges results in a mobile premaxilla that is only attached to the nasal septum and the labial soft tissues. It is also not uncommon to see only a limited bridge of bone (on one or both sides) connecting the lateral and premaxillary ridge after a previous bone graft. Unfortunately, this is inadequate bone volume into which the canine will erupt. In addition, a limited bone bridge cannot be relied on

• **Figure 33-2** A child who was born with bilateral cleft lip and palate and who had intact nasal sills. She was referred to this surgeon and underwent lip and palate repair during infancy. During the mixed dentition, she underwent successful bone grafting with stabilization of the premaxilla. The canines erupted through the grafted cleft sites and established a normal alveolar ridge. The lateral incisors were essentially normal and maintained within the arch form. With significant maxillary hypoplasia, the patient underwent a comprehensive orthodontic and orthognathic approach. Her procedures included Le Fort I osteotomy in three segments (correction of arch width and curve of Spee, horizontal advancement, vertical lengthening) with interpositional grafting; bilateral sagittal split ramus osteotomies (clockwise rotation); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal facial views before lip repair, after primary lip and palate repair, and at 8 years of age just before mixed dentition grafting.

After treatment

• **Figure 33-4, cont'd K,** Occlusal views before and after reconstruction.

• **Figure 33-5** A 17-year-old girl who was born with bilateral cleft lip and palate. She underwent lip repair by this surgeon during childhood. This was followed at another institution by cleft palate repair; a columella lengthening of the nasal soft tissues when she was 5 years old; a pharyngeal flap for the management of velopharyngeal insufficiency when she was 7 years old; and then bone grafting to the alveolar clefts when she was 8 years old. She was referred back to this surgeon when she was 17 years old and found to have cleft nasal deformities, chronic obstructed nasal breathing, severe maxillary hypoplasia, secondary deformities of the mandible, and retained wisdom teeth. The maxilla had been successfully grafted with orthodontic closure of the cleft dental gaps. The patient then underwent reconstruction by this surgeon, including maxillary Le Fort I osteotomy in two segments with differential repositioning (horizontal advancement +14 mm, vertical lengthening +5 mm, cant correction, and transverse narrowing) with interpositional grafting; bilateral sagittal split ramus osteotomies (asymmetry correction); osseous genioplasty (horizontal advancement); septoplasty, inferior turbinate reduction, and nasal base recontouring; and the removal of retained wisdom teeth. Before surgery, she underwent a nasoendoscopic speech assessment that demonstrated the satisfactory closure of the left lateral port with incomplete closure of the right lateral port (i.e., small air leakage). She maintained adequate velopharyngeal closure after surgery. Orthodontic maintenance and detailing continued and were followed by a removable maxillary retainer and a fixed lower anterior retaining wire. One year later, the patient underwent cleft rhinoplasty that included nasal osteotomies, the modification of the lower lateral cartilages, and a rib cartilage (caudal strut) graft. Note that ideal nasal aesthetics were compromised after a columella lengthening procedure that caused scarring of the soft tissues of the columella and distortions of the alar rims and tip. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

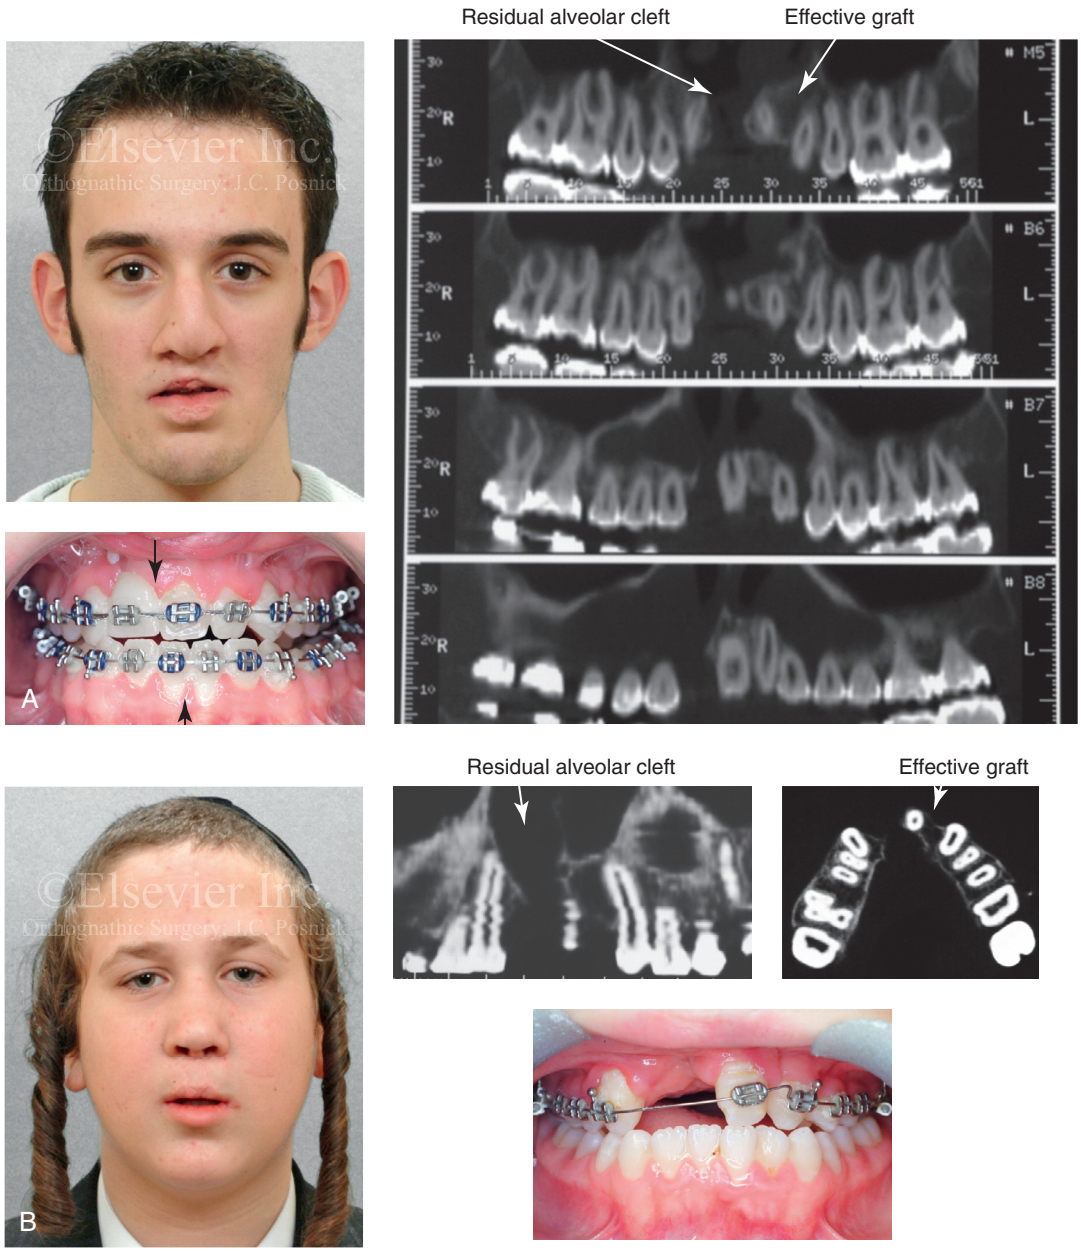
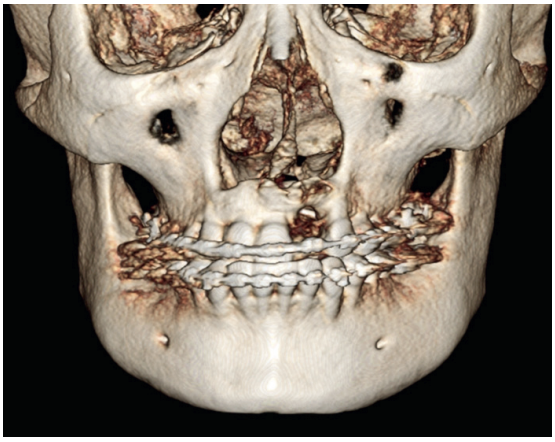
• **Figure 33-5, cont'd H,** Lateral cephalometric radiographs before and after reconstruction.



• **Figure 33-6** Three young adults who were born with bilateral cleft lip and palate are shown. Each had undergone bone grafting during the mixed dentition at another institution. Facial, occlusal, and computed tomography scan views indicate successful grafting at one cleft site but not at the other. It is important to make this determination when orthognathic surgery is required. If successful grafting was accomplished at one cleft site, then a circumvestibular incision can be made with full down-fracture, as one would for an ungrafted unilateral cleft alveolus. If successful grafting was not accomplished on either side, then a modified Le Fort I osteotomy in three segments would be required to maintain circulation to each of the three segments (i.e., the premaxilla, the left posterior segment, and the right posterior segment). This is done to avoid the complication of aseptic necrosis of the premaxilla (see Fig. 33-17). **A,** A teenager who was born with van der Woude syndrome and bilateral cleft lip and palate. He underwent successful grafting of one cleft site but not the other at another institution. He presented to this surgeon for orthognathic surgery. Facial, occlusal, and computed tomography scan views are shown. **B,** A teenager who was born with bilateral cleft lip and palate underwent successful alveolar grafting on the left side but not the right at another institution. He presented to this surgeon for orthognathic surgery. Facial, occlusal, and computed tomography scan views are shown and confirm these facts.



• **Figure 33-6, cont'd C,** A teenage girl who was born with bilateral cleft lip and palate underwent successful alveolar grafting on the right side but not the left. She then presented to this surgeon for orthognathic surgery. Facial and occlusal views when the previous patient was 7 years old, before grafting. **D,** Computed tomography scans of the same girl when she was 16 years old confirm successful grafting on right side but continued alveolar clefting on left side.

After palate repair
with large fistula

Residual cleft defects and mobile pre-maxilla

• **Figure 33-9** A 15-year-old girl was born with bilateral cleft lip and palate. She underwent lip and palate repair during infancy and early childhood by another surgeon. She retained a large oronasal fistula in the incisal foramen region from the time of the initial palate repair. She had worn a palatal prosthesis to obliterate the opening, but this interfered with speech articulation and oral hygiene. She was referred to this surgeon as a teenager and underwent a comprehensive orthodontic and orthognathic approach to close the large oronasal fistula, to stabilize the maxillary segments, and to restore her occlusion and periodontal health. As part of the preoperative orthodontic treatment, she underwent extraction of the five teeth for which there was inadequate alveolar bony support. During the operation, she underwent modified Le Fort I osteotomy in three segments with differential repositioning and interpositional grafting for closure of the large oronasal fistula, the cleft–dental gaps, and the alveolar defects. She also underwent septoplasty and inferior turbinate reduction to improve nasal airflow. Note that the maxilla was rehabilitated with the absence of the lateral incisors and a first bicuspid on the right side. **A,** Facial views before lip and palate repair. **B,** Palatal view during early childhood that indicates extensive oronasal fistula just after primary repair. **C** and **D,** Facial and palatal views at 15 years of age, when the patient was referred to this surgeon.

to provide circulation to the premaxilla at the time of a Le Fort I down-fracture through a circumvestibular incision.

5. *Chin dysplasia.* The patient with BCLP is often a forced mouth breather with an open-mouth posture. In addition, if a pharyngoplasty was placed for management of VP insufficiency, then a chronic open mouth posture may also be present. Secondary deformity of the chin often occurs as a result of the longstanding open-mouth posture during growth (see Chapter 4). The deformity is characterized by excess vertical height and horizontal deficiency (see Chapter 37).
6. *Mandibular dysplasia.* True mandibular prognathism is uncommon in the patient with BCLP. Mandibular ramus osteotomies should be used to correct secondary deformities such as facial asymmetry, skeletal disproportions, and the occasional true anteroposterior malformation.
7. *Nasal obstruction and sinus blockage.* Obstructed breathing through the nose and frequent sinusitis are typical in the individual who is born with BCLP. This results from a combination of septal deviation, enlarged inferior turbinates, tight nasal apertures, and scarred (collapsed) internal and external nasal valves (see Chapter 10). A pharyngeal flap may also contribute to nasal obstruction, mucous trapping, and sinusitis. The presence of obstructive sleep apnea should be considered and ruled out (see Chapter 26).
8. *VP dysfunction.* It is estimated that approximately 20% of patients with a repaired cleft palate demonstrate VP dysfunction by the time they are 5 years old. The adolescent patient with BCLP who arrives for the evaluation of a jaw deformity may have a pharyngeal flap in place. Despite the presence of a pharyngeal flap, the patient still may have VP dysfunction (see Chapter 8). Although a Le Fort I osteotomy with advancement is likely to improve the upper airway and speech articulation, it can have a negative impact on VP function. These disparate effects of the surgical plan should be taken into account and shared with the patient and the family (see chapter 8).

Orthodontic Considerations in the Bilateral Cleft Lip and Palate Patient with a Jaw Deformity

The patient with BCLP who has not undergone effective bone grafting during the mixed dentition will have three separate maxillary segments, each with a degree of dysplasia in all three planes. Each segment should be assessed and treated individually by the orthodontist in anticipation of segmental surgical repositioning. Radiographic analysis is essential before any orthodontic movement is initiated in the patient with BCLP. The Panorex film is useful for assessing the overall jaw, the dental anatomy, and the tooth angulation. Maxillary occlusal and periapical radiographs through the cleft sites are of some help, but a cone beam computed tomography scan is ideal to assess alveolar bone volume, including the height of the alveolar crest, the fenestrations and dehiscence of the walls, and, more importantly, the integrity of the alveolus across each cleft site.

Both the number of permanent incisors and the amount of dentoalveolar bone in the premaxilla differ widely. Lateral incisor-like teeth are frequently found along the edges of the premaxilla or the lateral segments. These are generally rudimentary, with poor root form, and they are best removed. Unerupted supernumerary teeth should be extracted either at the time of bone grafting during the mixed dentition or in conjunction with orthognathic surgery. A useful lateral incisor at the cleft site is only found in 7% of patients. The lateral incisor's usefulness should be assessed in accordance with root (rather than crown) morphology (see the discussion of orthodontic space closure versus prosthetic replacement later in this chapter).[13]

The decision to extract additional teeth in the lateral segments depends on the width and height of available alveolar bone and the degree of dental root crowding in each segment. Extractions of the first bicuspids may be necessary to ensure that there is adequate bone for leveling and aligning teeth in each lateral segment without irreversibly weakening the periodontal support of the dental roots next to the clefts.

The placement of preangulated brackets or artistic positioning bends can displace the root apices from their alveolar housing, with a rapid loss of crestal bone height along the mesial of the cuspid and distal of the incisor. Excessive mesial tipping of the canine should also be avoided. Some patients lack sufficient bone in the premaxilla to fully align the incisors preoperatively. In these cases, more complete orthodontic straightening is best accomplished after the cleft defects are surgically closed and healed.

The incorporation of all erupted and maintained maxillary teeth (including the second molars) into the orthodontic mechanics will facilitate the development of the desired postoperative arch form. A lingual attachment on the first molar band allows for the use of a transpalatal appliance for indirect anchorage to assist with bringing the second molars into alignment.

The development of an ideal mandibular arch is critical to the effective repositioning of the upper maxillary segments in the most favorable position at the time of orthognathic surgery. Extractions in the mandibular arch are generally not required, but this depends on the space requirements needed to position the incisors ideally over the basal bone.

Immediate Presurgical Assessment

Two to six weeks before the operation, the orthodontist will confirm that the preoperative orthodontic objectives have been met and place the passive surgical wires. The surgeon

then takes final records, including alginate impressions of the maxillary and mandibular arches, a centric bite registration, a face-bow registration, and direct facial measurements. Past medical and dental records (e.g., radiographs, consultation reports, facial and occlusal photographs, dental models, special studies) are reviewed. Computed tomography scan views of the cleft alveolus can be helpful to assess bone volume. Decisions are finalized regarding preferred vector changes of the jaws and the precise linear distances and angles to be accomplished in each jaw for the desired results (see Chapter 12).[2,37,38,74,75] Analytic model planning is carried out on the articulated dental casts, and splints are fabricated. The splints assist with the achievement of the precise occlusion and the preferred facial aesthetics that were determined preoperatively (see Chapter 13).

Orthognathic Approach for Bilateral Cleft Lip and Palate Deformities

Evolution of Surgical Technique

Surgical attempts to correct jaw disharmonies in patients with BCLP date back to Steinkamm's 1938 description of a Le Fort I osteotomy in a patient with BCLP.[123] The early literature warned of complications with maxillary osteotomy in patients with BCLP and offered incomplete descriptions of surgical techniques to guide the surgeon in the performance of safe and reliable osteotomies.[9,26-30,41,42,68] However, Hugo Obwegeser's milestone contributions to cleft skeletal reconstruction are important (see Chapter 2).[82-88] Although he succeeded in advancing a cleft maxilla to the preferred occlusion without the need for a mandibular set-back, other clinicians did not share his enthusiasm. Jackson and colleagues stated that patients with BCLP who required jaw surgery must first undergo successful fistula closure and bone grafting, and they postulated that "only then should a Le Fort I or Le Fort II procedure be considered."[61] Ward-Booth and others described a Le Fort II osteotomy that was designed to protect the circulation to the premaxillary segment.[135] In 1974, Willmar described the complications associated with the Le Fort I osteotomy.[138] Eight of the 106 patients in this study had BCLP, and one died after surgery. However, details of the operative technique were not mentioned. In 1980, Sinn described modifications for bilateral maxillary alveolar cleft repair in combination with Le Fort I osteotomy.[122] He suggested mobilization of the lateral segments and closure of the bilateral fistula with cheek flaps. Tideman and colleagues described at least one patient with BCLP who underwent a Le Fort I advancement through limited vertical incisions and subperiosteal tunneling for osteotomy exposure.[130] Westbrook and associates described simultaneous maxillary advancement and the closure of bilateral clefts and oronasal fistulas.[136] They used limited incisions with the objective of maintaining maximum blood supply to the lateral maxillary segments, but this prevented direct exposure of the maxillary walls and full mobilization. The authors did not mention surgical dental gap closure in the single patient with BCLP. James and Brook,[62] Poole and colleagues,[97] and others also described cleft–orthognathic techniques that involved the use of limited incisions and indirect exposure with subperiosteal tunneling. They believed that the staging of the fistula closure and the Le Fort I osteotomy was necessary to avoid premaxillary segment necrosis.

Posnick clarified the safety of segmental Le Fort I osteotomy techniques for patients with a BCLP jaw deformity. The documented favorable results confirm its value for the routine, one-stage management of those with a residual fistula, alveolar clefts, and dental gaps.[98-113] The technique is based on an understanding of the circulatory requirements of each of the three maxillary units in a patient who has not undergone a successful bone graft to unite the clefted segments. The authors confirmed that each of the three segments can be safely osteotomized, fully mobilized, and relocated in accordance with the patient's functional needs and aesthetic objectives. The premaxilla can be osteotomized (i.e., Vomer osteotomy) and raised as a dento–osseous–musculo–mucosa flap that is based on the labial mucosal pedicle. This technique was first described by Wunderer in 1962 and used extensively in patients without clefts.[144] Attention to detail is necessary to preserve the attachments of the labial soft-tissue–mucosal pedicle to the premaxilla. The validity of this flap's circulation was proven by Bell and colleagues in rhesus monkeys (see Chapter 2).[5] The labial soft-tissue pedicle ensures flap survival and safe repositioning of the premaxillary (dento–osseous–musculo–mucosa) segment.[7] The technique of maintaining a blood supply to the down-fractured posterior (lateral) segments after a direct circumvestibular incision was originally described by Schuchardt and later confirmed experimentally by Bell.[6]

Standard Le Fort I Osteotomy

The subgroup of patients with BCLP with intact alveolar ridges on one or both sides may have been born with bilateral clefts of their lips but with intact alveolar ridges on both sides, an intact alveolar ridge on just one side, or alveolar clefts that have been successfully grafted during the mixed dentition on one or both sides. For the adolescent or adult with BCLP who presents with a jaw deformity and intact alveolar ridges on both sides, a standard Le Fort I down-fracture can be carried out to correct the maxillary deformity (see Chapter 15) (Figs. 33-2 through 33-5). The adolescent with BCLP with an intact alveolar ridge on one side (the other side having residual alveolar clefting and an oronasal fistula) is essentially presenting with the same anatomy as a patient with unilateral cleft lip and palate who has not undergone any grafting. The surgical approach (technique) for this patient is the same as that described for the individual with an un-grafted unilateral cleft lip and palate (see Chapter 32) (Fig. 33-6). For all others born with BCLP and who present with un-grafted (open) alveolar clefts, the modified Le Fort I osteotomy in three segments

described in the next section should be considered (see Figs. 33-7 through 33-17).

Modified Le Fort I Osteotomy in Three Segments

Unfortunately, in current clinical practice, a percentage of patients with BCLP jaw deformities continue to present with alveolar clefts, residual oronasal fistulae, and mobile premaxillae. When completing a Le Fort I osteotomy in the BCLP patient with open alveolar clefts, specific incision placement is critical to maintain circulation to each of the three segments (see Figs. 33-7 through 33-17).

A buccal (labiolateral) incision is made on each side in the depth of the vestibule, which extends from the zygomatic buttress (just anterior and gingival to the parotid duct) forward to the location of the residual oronasal fistula. A vertical incision then continues down the mesial line angle of the canine (or, if the canine is missing, the most mesial tooth in each lateral segment). This mesial line angle vertical incision begins to separate the oral and nasal mucosa through the fistula. On the labial aspect of the premaxilla, a vertical incision then joins the more posterior vestibular incision and continues down along the distal line angle of the central incisor on each side to further separate the oral and nasal mucosa of the fistula. Care is required to prevent any disruption of or incision into the mucosa within the labial vestibule of the premaxilla.

The nasal and oral mucosa are also sharply incised and separated on the palatal aspect of the premaxilla and on the palatal aspect of each lateral segment. When this occurs, there is complete separation of all oral and nasal mucosa of the fistula. Care is taken to prevent any disruption or separation of the palatal mucosa from its underlying hard palate. Each lateral maxillary segment depends on this palatal soft tissue for circulation into the palatal bone.

Next, on the labial side, subperiosteal soft-tissue dissection exposes the anterolateral aspect of the maxilla of each lateral segment. A maxillary (Le Fort I type) osteotomy is then performed through the lateral, anterior, and medial maxillary walls using a reciprocating saw with a long, straight blade. The pterygomaxillary sutures are separated with a curved osteotome. The vomer is often not attached to either lateral segment. However, if it is, a guarded osteotome is used to separate it from the maxilla before the lateral segments can be successfully down-fractured. The lateral segments are then down-fractured and disimpacted for three-dimensional repositioning.

Next, attention is turned to completing an "out-fracture" of the premaxillary segment. The nasal mucosa is further dissected from the palatal mucosa on the posterior side of the premaxilla. The nasal mucosa and the soft tissues are pushed superiorly into the nose. An osteotomy is performed to free the premaxilla from the vomer. The osteotomy is generally performed using a reciprocating saw with a short, straight blade from the palatal side. It is imperative that the labial vestibule mucosa (pedicle) to the premaxilla remain connected to its underlying bone, because blood flows through this mucosa pedicle into the premaxillary bone and teeth. The nasotracheal tube is visualized and protected during the osteotomy that separates the vomer from the premaxillary flap. With the lateral segments down-fractured and the premaxillary segment out-fractured, the internal structures of the nose are directly visualized.

If the nasal septum is deviated, submucosal exposure allows resection of the obstructing portions of the vomer, the perpendicular plate of the ethmoid, and the quadrangular cartilage using a rongeur. The structural components of the quadrangular cartilage (i.e., the dorsal and caudal strut) are preserved to prevent a late saddle deformity. The inferior turbinates, if enlarged, are reduced along the whole inferior aspect of the turbinate. The raw surfaces are then cauterized for hemostasis. The reduction of hypertrophic inferior turbinates will both facilitate nasal-side mucosal flap closure and improve nasal airflow after healing. The nasal mucosal flaps are sutured to obtain as watertight of a nasal-side closure as possible.

The lateral maxillary segments are ligated into the prefabricated acrylic occlusal splint. This is followed by the ligation of the premaxillary segment. Through this procedure, the cleft–dental gap on each side and the dead space associated with the bony clefts are closed. To accomplish dental gap closure, it is generally necessary to remove spurs of alveolar bone at the interface of the lateral and premaxillary segments using a rotary drill with a small watermelon bur. This is done without perforation through the lamina dura, which could injure the dental roots. The differential advancement of the lateral segments also approximates the labial and palatal mucosal flaps for effective oral-side fistula closure. The suturing of the palatal mucosa is not necessary, because the segmental repositioning approximates the freshened mucosal edges along the palate. The palatal mucosa must remain adherent to the underlying bone to ensure adequate circulation to each of the lateral segments. All three segments are now secure in the prefabricated acrylic splint.

The maxilla, which has been secured to the splint, is advanced and repositioned to the mandible. The jaws are then secured together with intermaxillary fixation. The preferred vertical dimension, which was determined preoperatively, is achieved to improve the facial height and the lip-to-tooth relationships. Titanium plates are conformed across the osteotomy sites at each zygomatic buttress and each pyriform aperture and then secured with screws. The intermaxillary fixation is released, and the occlusion is checked.

The intermediate splint is removed and the lateral segments are secured with wires into the final splint. A small amount of autogenous (iliac) cancellous bone graft is packed along the floor of the nose and the cleft (hard) palate on each side before securing the premaxilla into the final splint. The dead space associated with the alveolar cleft will be effectively closed once the premaxilla is secured into the splint.

A bloc of corticocancellous iliac bone is crafted and interposed along the bony gap created on each side when the lateral segments were advanced. The graft is placed between the zygomatic and pyriform plates. An additional microplate is placed from the superior maxilla, across the graft to the inferior maxilla, and then secured with screws. With the cleft–dental gaps surgically closed, the labial gingival mucosa on each side is directly approximated without the need for mucosal advancement flaps. If indicated, mandibular and chin osteotomies and removal of wisdom teeth are completed in the usual sequence and then fixed in place (see Chapter 15).

After wound closure, the occlusion is maintained with elastics. The elastics may be removed for immediate postoperative airway management and then reapplied as indicated. Maintenance of the occlusion and retraining of the muscles are accomplished with intermittent elastics during the next 5 weeks. For the modified Le Fort I osteotomy in three segments, the splint frequently remains ligated to the maxillary orthodontic brackets for a total of 7 weeks. At the time of splint removal, the orthodontist replaces the segmented maxillary surgical wires for a continuous rigid one. The treating orthodontist actively maintains the surgically achieved arch form and cleft–dental gap closures. The placement of a transpalatal appliance secured into the lingual tubes on the maxillary first molar bands may be a useful adjunct to maintain the arch form after the splint is removed.

Avoiding Pitfalls

Mobilization of the Down-Fractured Cleft Maxilla

Full mobilization of the Le Fort I osteotomy in the patient with BCLP is the critical step needed for the achievement of accurate intraoperative positioning and then long-term maintenance of the maxilla. The intraoperative use of both pterygoid and nasomaxillary disimpaction forceps is important for full mobilization. Taking the necessary time to slowly complete the disimpaction (10 to 15 minutes) is often crucial to the achievement of the desired results. Gaining experience—first through observing and assisting an experienced cleft orthognathic surgeon and then by using one's own hands—is essential to achieving confidence in the mobilization process.

Horizontal Advancement and Vertical Lengthening of the Cleft Maxilla

The surgeon must often carry out significant advancement and vertical lengthening of the BCLP maxilla to fully enhance facial aesthetics, to correct the occlusion, and to open the airway. Scarring of the palatal soft tissues from previous repairs may be of concern when considering significant advancement.

In general, to achieve full skeletal correction, all or most of the negative overjet should be managed in the maxilla. Most deficient BCLP maxilla will also require vertical lengthening. A repaired bilateral cleft lip that has minimal elevation with smile or that appears short and hypotonic may caution the surgeon against the vertical lengthening that the midface requires. The surgeon should fight the tendency to "underlengthen" the midface.

After the maxilla is fully mobilized and positioned, as described previously, stabilization is with titanium plates and screws (a plate with screws at each zygomatic buttress and pyriform rim).[71] The placement of a bloc corticocancellous graft wedged into the dead space between the zygomatic buttress and the pyriform rim plate on each side is generally necessary (see Chapter 18). Further stabilization across each graft with a titanium microplate and screws is also required (see Chapter 15). When a modified (three-segment) Le Fort I osteotomy is carried out, the soft-tissue pedicle that provides circulation to each bone flap must be protected during mobilization, graft placement, and stabilization, as described previously.

Closure of Residual Oronasal Fistula and Alveolar Cleft Management

Ideally, full closure of residual oronasal fistula and adequate alveolar bone grafting will have been carried out during the mixed dentition. If not, the modified Le Fort I in three segments (as described previously) for the patient with BCLP provides the opportunity for complete oronasal fistula closure on both the palatal and labial sides, the management of the cleft skeletal deficiencies, and the stabilization of the premaxilla without the need for direct alveolar grafting. Not uncommonly, grafting and fistula closure were carried out during the mixed dentition, but with only partial success. A residual fistula may remain, and the premaxilla may not have union with one or both lateral segments. Unfortunately, when completing a Le Fort I procedure in the patients with BCLP with residual fistula and non-bridging alveolar ridges, fistula closure and union across the ridge can only be accomplished with the use of the modified segmental approach, as described previously. Augmentation of an intact but hypoplastic alveolar ridge at the time of down-fracture is not advisable, because additional soft-tissue dissection around the alveolar ridge would be required with a risk of compromised circulation and aseptic necrosis. The option of placing a corticocancellous bloc graft into the alveolar defect at the time of Le Fort I down-fracture is also not feasible for the same reasons.

Managing the Nasal Cavity and the Nose

In the patient with BCLP, the inferior turbinates are generally enlarged and partially blocking the nasal cavity. If so, the reduction of the inferior turbinates will be beneficial for breathing and sinus drainage; this is simultaneously accomplished through the down-fracture (see Chapter 15 and illustrations in this chapter).

In the patient with BCLP, the septum (bone and cartilage) may be significantly deviated, thus further obstructing the airway. The completion of a submucosal resection to open the airway with preservation of the caudal and dorsal cartilaginous struts to prevent a saddle deformity is beneficial. This is accomplished through the Le Fort down-fracture (see Chapter 15 and illustrations in this chapter).

In the patient with BCLP, the pyriform rims and the nasal floor may be irregular, which results in negative effects on the airway and the nasal aesthetics. If successful grafting had previously been accomplished, recontouring of the pyriform rims, the nasal floor, and the nasal spine using a rotary drill with a watermelon bur through the circumvestibular incision is helpful to open the airway and to improve nasal aesthetics. This cannot be simultaneously accomplished with the three-segment modified Le Fort I procedure in these patients (see Chapter 15 and illustrations in this chapter).

Surgical attempts to control the nasal soft-tissue envelope with suturing techniques (e.g., the alar cinch stitch) after Le Fort I osteotomy are often suggested. In my experience, manipulating the nasal soft tissues with suturing techniques at the time of Le Fort I osteotomy in the patient with BCLP is often counterproductive to both the airway and the aesthetics, because it does not address the primary problem, as described previously. We anticipate that the nasal soft tissues will redrape over the repositioned and recontoured maxilla and the nasal base to result in an overall improvement in aesthetics. A definitive rhinoplasty is usually planned for 6 to 12 months after jaw surgery (see Chapter 38).

Immediately after surgery, the nasal cavity is not packed, and the septum is not stented. It is expected that coagulated blood will partially block the airway. The clots will dislodge and be self-eliminating by approximately 5 to 7 days after surgery. The use of saline nasal sprays and the institution of sinus precautions are both helpful during this time (see Chapter 11).

Management of the Mandibular Deformity

In the patient with BCLP, the mandible is often secondarily deformed. In a previously published study, we documented that, in a significant percentage of individuals with BCLP, the lower jaw will also benefit from sagittal split ramus osteotomies to improve facial symmetry and proportions.[108,112,113] The mandibular repositioning is not carried out in an attempt to avoid maxillary advancement but rather to improve overall morphology (see Chapter 15).

Management of the Chin Deformity

In the BCLP patient with maxillary hypoplasia, the chin is often secondarily deformed. Increased vertical length and a flat pogonion are typical. If these are present, an intraoral oblique inferior border osteotomy is simultaneously carried out with repositioning of the distal chin to accomplish the preferred morphology (see Chapters 15 and 37).

Clinical Management after Initial Surgical Healing

Managing the details of the in-hospital and at-home convalescence during initial healing is essential for a successful outcome after BCLP orthognathic surgery (see Chapter 11). Cephalometric and dental radiographs and facial and occlusal photographs are obtained at standard postoperative intervals to document clinical progress. The orthodontist sees the patient within 24 hours of splint removal (approximately 5 to 7 weeks after surgery) and replaces the maxillary sectional arch wires with a rigid continuous arch wire. The maxillary teeth are ligated together to maintain the surgical dental–gap closure and the overall arch form. Active orthodontic maintenance and finishing are started. The use of a transpalatal appliance (i.e., a wire or a palatal plate) may also be used to further stabilize the new arch form. Close monitoring by an orthodontist for skeletal and dental shifts during the first 6 months after surgery is essential.

Speech can be objectively reassessed 3 to 6 months after surgery. We prefer to evaluate VP function with the use of nasoendoscopic instrumentation when feasible. Definitive cleft soft-tissue procedures (e.g., cleft rhinoplasty, lip scar revision, pharyngeal flap or flap revision) can be carried out as early as 6 months after orthognathic surgery. After the orthodontic appliances are removed, any planned definitive dental restorative work can be finalized.

Orthognathic Surgery for Bilateral Cleft Lip and Palate: Review of Study

Patients and Methods

Posnick and Tompson assessed the clinical results of 33 consecutive adolescents (age range, 16 to 24 years; mean, 18 years) with BCLP who underwent orthognathic surgery by a single surgeon (Posnick) over a 6-year period using the modified Le Fort I osteotomy as described previously.[113] All patients underwent perioperative orthodontic treatment, and all were judged to be skeletally mature at the time of jaw surgery. The clinical follow-up period ranged from 1 to 7 years (mean, 40 months) at the close of the study. The country of origin of the patients varied (e.g., Canada, United States, Eastern Europe, Southeast Asia), as did their race (e.g., Caucasian, Asian, African). The patients' initial surgeons varied, as did their treatment protocols. All patients had undergone primary lip and palate repair during infancy. The number and extent of other operations (i.e., soft-tissue, lip, nasal, and palatal procedures) varied greatly (range: 1 to 10 procedures). Many patients had undergone additional

attempts to close the residual oronasal fistula as well as bone grafting to fill the alveolar clefts. The basic orthognathic procedures that were carried out included a modified Le Fort I osteotomy (n = 33). Ten of these patients also underwent simultaneous sagittal split ramus osteotomies of the mandible to correct secondary deformities. Fourteen underwent osseous genioplasty (vertical reduction and horizontal advancement) of varying degrees to improve profile aesthetics and lip posture.

In the study group, all of the patients with BCLP required closure of residual bilateral labial and palatal fistulas. Twenty-six of the 33 patients had a negative overjet of the incisors, which indicated horizontally maxillary hypoplasia. Twenty-eight of the 33 patients also had posterior crossbites in the lateral (lesser) segments, which indicated constriction of the maxillary arch despite orthodontic treatment. Thirty patients had a cleft–dental gap on each side, and one to three teeth were missing at each cleft site; one patient had a cleft–dental gap on just one side; and the remaining two patients had undergone successful gap closure via orthodontic treatment but had residual fistula and alveolar defects. For the 30 patients with bilateral cleft–dental gaps, simultaneous surgical closure via the differential advancement of the maxillary segments was planned. All 33 patients had mobile premaxillae, thereby indicating inadequate bone bridging across the cleft alveolar regions on each side. Of the 66 cleft sites, 59 had either congenitally absent or inadequate lateral incisors. Ninety-three percent of patients had an Angle Class III malocclusion on each side.

Results

All 33 adolescent patients with BCLP patients presented with residual oronasal fistulae, mobile premaxillae, and maxillary hypoplasia.[113] Twenty-six patients underwent successful one-stage complete fistula closure and full stabilization of the premaxillary segment through modified Le Fort I osteotomy, with differential maxillary segmental repositioning. The seven patients who retained small fistulas (all in the incisive foramen region) also retained a degree of mobility of the premaxillary segment. Final fistula closure involved the use of local flaps with additional bone grafting to achieve bony union of the premaxilla to the lateral segments.

All 33 patients successfully achieved and maintained keratinized gingiva over the cleft site and the cleft-adjacent teeth on each side. A degree of gingival recession occurred along the medial aspect of the canine (or the first premolar when the canine was absent) or the distal aspect of the incisor in 7 of the 132 cleft-adjacent teeth. None of the cleft-adjacent teeth required root canal therapy. Five patients required fixed prostheses to either replace missing teeth or to improve the aesthetics of the incisors as a result of poor enamel quality or congenital dysplasia. Thirty-one patients who had cleft–dental gaps underwent successful closure. In three patients, both the lateral incisor and the canine were missing, and a "closed down" but residual gap was planned. Dental restorative work was then carried out. Two other patients had undergone the orthodontic completion of gap closure.

The long-term maintenance of overjet and overbite was measured directly for each patient from the late (>1 year) postoperative lateral cephalometric radiograph. Most patients (31 of 33; 94%) maintained a positive overjet. Two of the 33 patients (6%) shifted into neutral overbite, and 4 of the 33 patients (12%) relapsed into a negative overbite. There were no cases of infection that required the extended use of antibiotics or drainage, and there was no postoperative hemorrhage that required a return to the operating room. No teeth or dentoalveolar segments were lost to aseptic necrosis, direct surgical trauma, infection, or any other cause. No patients underwent reoperation (orthognathic procedures) for suboptimal facial aesthetics or significant residual malocclusion.

Controversies and Unresolved Issues

Staging of Maxillary Reconstruction

The described modified Le Fort I osteotomy method for the management of the maxillary deformity in an adolescent or adult patient with BCLP who also presents with missing teeth, oronasal fistulae, alveolar defects, cleft–dental gaps, and nasal obstruction is not intended to replace standard techniques and the accepted sequencing of treatment earlier during childhood.[99] However, it does offer an effective reconstructive option after the opportunity for grafting the alveolus during the mixed dentition before the eruption of the permanent canines is lost and if a jaw deformity coexists. A two-stage approach for the adolescent with BCLP with maxillary hypoplasia, residual alveolar clefts, oronasal fistulae, cleft–dental gaps, a mobile premaxilla, and nasal obstruction is neither cost-effective nor time-efficient, and there may be increased morbidity. It is in these patients with BCLP that the modified Le Fort I osteotomy in three segments with the differential repositioning of each segment offers a reasonable opportunity for correction.[98-113]

Closure of Large Residual Palatal Fistula

Other indications for maxillary segmental osteotomies include the small group of adults (i.e., those in the permanent dentition) with BCLP who may have a satisfactory overjet or overbite but who have large residual palatal and bilabial fistulae, cleft–dental gaps, and mobile premaxillae. The difficulty in achieving successful fistula closure is the lack of oral-side soft tissue to secure a watertight palate closure in the incisal foramen region. In general, there are only two surgical options for management. One consideration is an anteriorly based dorsal tongue flap that is combined with an autogenous bone graft. If the size of the

fistula, the amount of dead space, and the tissue deficit is extensive, even a tongue flap and a bone graft will likely fail. The best option in these difficult cases is to obturate the fistula and to maintain the cleft–dental gaps with a temporary partial denture until early skeletal maturity (i.e., adult dentition). A modified Le Fort I osteotomy (either two or three segments) with differential repositioning is then performed. By advancing the lateral segments, closure of the fistula, dental gaps, and dead space can generally be achieved (Fig. 33-9). If there is horizontal, transverse, or vertical deficiency or deformity of the maxilla, it is simultaneously managed.

Management of Complex Dental Rehabilitation

Another indication for the modified Le Fort I osteotomy (two or three segments) in the adult with BCLP is to assist with complex dental rehabilitation when excessive cleft and congenital anodontia gaps exist, with or without residual fistula. There are times when horizontal maxillary projection may be satisfactory; however, a functional arch form can best be achieved through segmental Le Fort I osteotomies that are planned in conjunction with dental rehabilitation (Fig. 33-15).

Malocclusion after Modified Le Fort I Osteotomy

Despite the advantages of the described modified Le Fort I osteotomy for complex BCLP deformities, there are two occasional unresolved long-term shortcomings of this procedure. The first is the tendency for medial, superior, and posterior drift (relapse) of the lateral segments after surgical correction. To combat this relapse pattern, planned surgical overcorrection as well as rigid transverse maintenance early after surgery with an acrylic splint and then medium term (6 months) orthodontic retention techniques are essential. The second unresolved problem is the less than ideal success rate of 80% to 85% for complete fistula closure and premaxillary segment stabilization to the lateral segments. This is a result of the limited bone volume of the premaxilla in many patients and the inability to apply plate and screw stabilization (i.e., of the premaxilla to each lateral segment) without compromise of the anterior maxillary circulation, which is dependent on the labial mucosa pedicle.

Philosophy Concerning the Importance of a "28-Tooth Angle Class I Occlusion"

Another controversy for the reconstruction of the patient with BCLP centers on a philosophy of the importance of achieving a "28-tooth Angle Class I occlusion" with traditional "cuspid protection" rather than accepting "group function" during lateral excursions.[10,45,49,119,124,126,127] The achievement of a 28-tooth occlusion would require non-extraction therapy and the maintenance of each cleft–dental gap (i.e., lateral incisor region), followed by a single-tooth dental implant placement or the use of another prosthetic option. Unfortunately, in the maxillary-deficient patient with BCLP, dental crowding generally exists, and extractions or closure of the dental gaps will be required to avoid long-term periodontal sequelae.

In a non-cleft population, only a few studies compare the results of orthodontic space closure (OSC) with prosthetic replacement for the management of congenitally absent maxillary lateral incisors. The absence of high-quality clinical research to evaluate an implant replacement option (as apposed to a bridge) continues to fuel the discussion of what constitutes the optimal treatment of a missing lateral incisor in the patient with a cleft. It has been documented in several studies that, for an individual with an alveolar cleft, OSC results in a healthier periodontium and greater patient satisfaction than classic prosthetic replacement.[81] OSC in patients with clefts after successful alveolar bone grafting has the added advantage of allowing the canine to be positioned into the lateral incisor location, thereby resulting in an improved alveolar ridge morphology.[1,22] A single-tooth dental implant option for the management of the cleft–dental gap in the patient with BCLP is an attractive theoretical alternative, but it requires the presence of an intact maxilla (i.e., the stability of the premaxilla to each lateral segment) with adequate alveolar bone volume, interproximal crestal height, and sufficient attached gingiva at each cleft site for favorable implant placement, dental aesthetics, and long-term maintenance.[49,72,91,93,115,116,128,129,133,134,146]

Unfortunately, these anatomic parameters are not often met in patients with BCLP. Furthermore, these dental procedures are rarely covered by medical insurance, which adds to the family's financial burden. This approach also requires the meticulous coordination of a spectrum of dental specialists (e.g., orthodontist, periodontist, prosthodontist, surgeon) who have expertise and dedication in the area of cleft deformity treatment. Even if implant placement and crown restoration are successful, this will create a long-term high-maintenance dentition for the patient. This combination of factors usually favors OSC when feasible or surgical space (dental gap) closure (via modified Le Fort I osteotomy) when appropriate. OSC is preferably accomplished by successful mixed-dentition grafting and orthodontic dental gap closure. Oosterkamp and colleagues completed a retrospective study of adults with BCLP who were missing a permanent lateral incisor at each cleft site.[89] The patients were treated either with orthodontic space closure (n = 17) or via prosthetic replacement (n = 10). The purpose of the study was to compare the dental aesthetics and function of OSC versus those of the prosthetic replacement of the lateral incisors in patients with BCLP. The predominant mode of prosthetic replacement was resin-bonded bridges. Dental aesthetics were evaluated by the patients themselves and by a professional panel. Mandibular function was evaluated by means of the standardized

Mandibular Function Impairment Questionnaire. The level of mandibular impairment was calculated with the use of the standardized Functional Impairment Rating Scale. With respect to dental aesthetics, no significant differences between patients treated with OSC and prosthetic replacement were found. With respect to function, the level of mandibular impairment was significantly higher among patients who were treated with prosthetic replacement as compared with those treated with OSC.

Velopharyngeal Function after Le Fort I Advancement

Uncertainties about VP function and the management of an in-place pharyngeal flap should no longer be limiting factors when orthognathic surgery is necessary in a patient with BCLP. A nasoendoscopic guided examination by a speech pathologist and a surgeon who is familiar with cleft anatomy can closely predict current and expected VP function in a patient who is scheduled for a Le Fort I osteotomy (see Chapter 8). When postoperative VP deterioration is anticipated, the patient and the family are counseled about the sequencing of treatment. Clinical studies have now documented that VP function will deteriorate in a similar fashion when either DO or standard Le Fort I osteotomy techniques are used in the patient with a cleft patient.[14,15,44,47,63,67,73,76,94,131] Despite the frequent need for significant maxillary advancement to normalize the skeleton and the facial aesthetics of patients with BCLP, we have not had to or seen an advantage to transecting an in-place pharyngeal flap to achieve maxillary mobilization and the desired advancement. Our research and that of others confirms that a pharyngeal flap in place at the time of Le Fort I osteotomy does not increase complications nor does it result in a higher incidence of relapse.[113] The definitive reassessment of VP function after cleft Le Fort I advancement can be carried out 3 to 6 months after surgery. A primary or revision pharyngeal flap can be carried out 6 months after orthognathic correction in conjunction with cleft rhinoplasty or labial revision, if indicated.

Mixed-Dentition Le Fort I Osteotomy

By the mid 1980s, research clarified that, if jaw surgery is undertaken during the mixed dentition in the patient with a cleft palate, then another procedure to advance the maxilla will likely be required after skeletal maturity is reached.[140-144] More recently, several investigators again tested this theory by proceeding with mixed-dentition Le Fort I osteotomies in these patients using DO techniques.[16,34,35,46,48,59,95] All research to date indicates that the Le Fort I advancement carried out during the mixed dentition in the patient with clefting—whether by standard or DO techniques—results in no further significant horizontal growth. If the mandible continues to grow in length, an Angle Class III malocclusion will occur with the need for additional Le Fort I advancement or mandibular set-back.

Skeletal Relapse after Le Fort I Osteotomy in Patients with Clefting

There are more than 100 published articles reviewing skeletal stability and relapse in patients with clefting who have had Le Fort I advancement with the use of either standard osteotomies or DO techniques.[3,11,12,17-19,31,32,39,40,51,54-58,60,65,70,78,96,125,139] These studies do not demonstrate convincing differences in relapse patterns between the two techniques. Proponents of DO techniques frequently state that, when more than 10 mm of maxillary advancement is required, the use of standard Le Fort I osteotomy techniques with plate and screw fixation and bone grafts may lead to a greater degree of relapse. To put this in perspective, it should be noted that only 5% of patients with clefting who are undergoing Le Fort I advancement will require 10 mm or more of horizontal advancement at the incisors. All clinicians will agree that this subgroup of cleft patients (5%) is the most challenging. The reasons for this go beyond the degree of horizontal maxillary deficiency. These patients are also likely to present with multiple residual end-stage deformities (see the section about residual skeletal deformities earlier in this chapter) and previously failed surgical procedures. Aksu and colleagues documented a horizontal maxillary relapse rate of 22% after Le Fort I osteotomy in patients with clefting who were treated with DO techniques.[4] This was found at the 3-year follow-up evaluation in a series of adult patients with repaired cleft lips and palates who presented with maxillary hypoplasia.

He and colleagues reported their results of treating adolescents with repaired cleft lip and palate and maxillary hypoplasia with Le Fort I advancement via an external DO device.[50] The patients (n = 17) were treated at one center between 2000 and 2006 and had at least 1 year of follow up and a full set of records. DO treatment started on day 5 (1 mm/day) and continued until a Class II occlusion (overcorrection) was achieved. Consolidation time ranged from 4 to 12 weeks, and this was followed by several more months of face mask therapy. The first four treated patients—two with unilateral cleft lip and palate and two with BCLP—developed fibrous non-union; all four required reoperation and rigid fixation to achieve bony union. The authors then extended the consolidation period to a minimum of 12 weeks for the remaining patients (n = 13), at which point all patients had achieved bony union. In the group that achieved satisfactory bony union (13 out of 17 patients; 76%) the mean horizontal relapse was 11.9%, with 5 out of 13 patients (38%) developing no better than "end-to-end" occlusion. Another orthognathic procedure was necessary to obtain a satisfactory occlusion in 5 of the 13 patients (38%) who had initially achieved bony union. Overall, 9 out of 17 patients (53%) required two orthognathic procedures.

In 2011, Chen and colleagues reported a 30.7% incidence of horizontal relapse after Le Fort I osteotomy with the use of DO techniques in patients with clefting who

presented with Class III malocclusion.[16] Interestingly, Posnick and colleagues documented a more limited degree of horizontal relapse and overall success when using the modified Le Fort I techniques described for cleft patients.[113] Stability and relapse were measured by a review of postoperative (≥1 years) cephalometric analysis and clinical examination.[113] This was reported by cleft type: 94% of patients with BCLP maintained a positive overjet long term; those with unilateral cleft lip and palate achieved 6.9 mm of advancement, with 5.3 mm maintained for the long term; and those with isolated cleft palate (ICP) had 6.1 mm of advancement, with 5.1 mm maintained over the long term. All of the ICP patients maintained positive overjet long-term.

Standard Approach versus Distraction Osteogenesis Approach to Le Fort I Advancement

I agree with Obwegeser when he stated the following: "Today, many surgeons will resort to the use of distraction devices to gradually advance the cleft maxilla. Although in some circumstances this may be appropriate, it should be remembered that most cleft patients can be treated efficiently, even when requiring significant advancement with the classic Le Fort I type procedure as described."[87]

Standard thinking is for the surgeon to commit to an approach (DO versus standard technique) for Le Fort I advancement before he or she arrives in the operating room. The surgeon then sticks to the plan, no matter what happens intraoperatively. On the basis of a review of the literature and almost three decades of personal experience as a cleft jaw surgeon, I make the following observations and recommendations in this area.

Observations About the Distraction Osteogenesis Approach

- DO techniques are always the patient's second choice when compared with the standard approach of Le Fort I osteotomy and rigid internal fixation. The length of downtime after surgery involving DO is longer (≥3 months of limited diet and physical activity), and it is followed by several additional months of face mask therapy. There is no reduction in the perioperative complications when using DO techniques rather than standard techniques. The device is also awkward and socially embarrassing, and it typically blocks the patient's visual fields (e.g., the RED, BLUE, or GREEN external DO devices).
- If the cleft maxilla is down-fractured, adequately mobilized, and stabilized with interpositional bone grafts and plate and screw fixation, it has a high probability of healing as planned with a predictable and less extensive convalescence than DO.
- An experienced cleft orthognathic surgeon will be more confident in his or her ability to down-fracture and fully mobilize the BCLP maxilla than a less experienced surgeon. Therefore, the less experienced surgeon will be more likely to choose DO techniques to avoid the personal stress of the intraoperative maxillary mobilization process.
- Even for the experienced cleft orthognathic surgeon, there will be the occasional patient in whom the extent of maxillary hypoplasia and associated deformities (e.g., missing teeth, lack of alveolar bone, residual fistula) will lead him or her to choose DO techniques. Despite its protracted healing requirements and its limited ability to correct all of the cleft deformities, the DO device's gradual stretching ability can mobilize even the most recalcitrant maxilla (see Fig. 32-21).

Recommendations for the Distraction Osteogenesis Approach

For most patients with BCLP and maxillary hypoplasia, reserving DO techniques to serve as a "bail out" when the down-fractured maxilla cannot be adequately mobilized is the approach that I recommend. The patient and family at risk can be informed of this contingency plan in advance. This approach allows the surgeon to have flexibility in the operating room to make the right decision at the right time for the patient in need to achieve the most efficient convalescence and the most favorable long-term objectives.

Conclusions

Clinical studies document a high prevalence of jaw deformities in mature patients with BCLP. Safe and reliable surgical methods are now available to manage the presenting cleft jaw deformity, malocclusion, and other simultaneous residual defects (e.g., oronasal fistulae, bony defects, cleft–dental gaps, nasal obstruction). These techniques offer the surgeon an opportunity to improve the patient's head and neck function, to enhance the patient's facial aesthetics, and to positively affect the patient's long-term quality of life and well-being.

Isolated cleft palate (ICP) is a separate entity from cleft lip and palate. ICP has a different genetic pattern and associated anomalies, and it involves unique intraoral and facial anatomy and its own potential for head and neck dysfunction. It is estimated that approximately 30% of individuals born with cleft palate only (i.e., no cleft lip or alveolus) will have other associated malformations or be part of a known syndrome. Patients with ICP have a variety of jaw, dental, upper airway, and speech-related needs during childhood and into adolescence. The surgical repair of cleft palate during infancy with revision later in childhood, when it is needed to ensure adequate velopharyngeal competence, may result in disturbed growth of the upper jaw.

Facial Growth Implications of Cleft Palate Repair in the Infant with Isolated Cleft Palate

Ross documented that at least 20% of Caucasian individuals with ICP who undergo repair during infancy will experience maxillary hypoplasia that results in malocclusion that is not responsive to either traditional or compensatory orthodontic maneuvers alone.[86] Chen and colleagues reported on horizontal maxillary growth in both children and adults with Eastern Chinese ethnic backgrounds and with unoperated and operated ICP.[14] There were two study groups: individuals in Group 1 had non-syndromal and unoperated ICP that was evaluated during the mixed dentition (n = 16); individuals in Group 2 had non-syndromal and unoperated ICP that was evaluated during the permanent dentition (n = 25). The control groups included patients with ICP who underwent repair during childhood as well as non-cleft individuals with Class I occlusion that was evaluated during both the mixed and permanent dentitions. Lateral cephalograms of all subjects were analyzed. The results of the mixed dentition groups showed almost normal sagittal growth in unoperated patients except for the reduced anterior-posterior maxilla length. In contrast, the operated patients showed reduced length of both the maxilla and mandible, as well as a clockwise rotation of the mandible. The analysis of the permanent dentition groups showed that in both the unoperated and operated ICP patients, there were reductions in maxilla length, mandibular protrusion, and maxillary retrusion. Interestingly, there appeared to be no correlation between maxillary growth restriction and the extent of the congenital clefting of the secondary palate (i.e., soft palate only versus hard and soft palate). The authors concluded that, for individuals born with ICP, the etiology of the maxillomandibular deficiency likely results from a combination of factors, including the intrinsic primary (cleft) defect; secondary hypoplasia as a result of the surgical repair during infancy (iatrogenic); and functional (environmental) factors (e.g., the effects of muscles of mastication, respiratory patterns, mandibular

rest posture; see Chapter 4). These results were similar to those of Yoshida and colleagues, who found that individuals with ICP frequently end up with maxillary horizontal deficiency and clockwise rotation of the maxillomandibular complex that tend to become worse as the child reaches adulthood.[99]

A significant percentage of adolescent patients who were born with ICP will present with a jaw deformity that requires, at minimum, a maxillary Le Fort I (down-fracture) osteotomy to align the jaws.[5,85] When indicated, this is combined with mandibular and chin osteotomies to achieve improved facial proportions and with intranasal procedures (i.e., septoplasty and inferior turbinate reduction) to improve nasal breathing.

Coordinated Team Approach

The facial reconstructive and dental rehabilitation of an individual with ICP is best delivered via collaborative care provided by appropriate medical and dental specialists.[6,62,71] It is no longer justified for individual practitioners—whether they are surgeons, orthodontists, restorative dentists, speech pathologists, or otolaryngologists—to carry out extensive treatment without informing the patient and his or her family of available options and considering clinical input from the other specialists who are caring for the patient.

Treatment Protocol

Patients who are referred for possible orthognathic surgery are seen by an orthodontist, an orthognathic surgeon, a speech pathologist, and an otolaryngologist. Consultation with other medical (e.g., sleep specialist, geneticist) and dental (e.g., periodontist, restorative dentist) specialists may also be indicated. Initial records and tests include, at minimum, medical-quality photographs, including views of the face and the occlusion; cephalometric and Panorex radiographs; dental models with centric bite registration; speech assessment with instrumentation (ex. nasoendoscopy); and a thorough evaluation of the upper airway. Discussions with the medical and dental consultants, the family, and the patient are needed to set the clinical objectives. Decisions about the timing and extent of the orthodontic, surgical, and dental treatments are made in an effort to reach the chosen objectives.

The primary cleft surgeon completes the patient's palate repair during infancy, and this is followed by pharyngeal procedures later during the patient's childhood if they are required to improve velopharyngeal function. The surgeon is also likely to play an important role in directing the patient's care throughout adolescence and into adulthood. If the cleft surgeon is not trained in skeletal procedures, then a timely and seamless transition to the maxillofacial surgeon who will continue on with the patient's reconstruction is necessary. The orthodontist identifies early abnormal facial growth patterns and may carry out interceptive treatment.[6,10,11,18,19,27,34,51,55,64,65,87,90,91] Definitive orthodontic treatment is coordinated with orthognathic surgery, when indicated.[33] Extensive compensatory orthodontic treatment is likely to jeopardize periodontal health and to lead to dental relapse with recurrent malocclusion. Camouflage orthodontics should be avoided for these reasons and only be entered into with full disclosure to the family and other treating clinicians.

Before orthognathic surgery is performed, the speech pathologist performs an evaluation to assess the patient's velopharyngeal function; this will ideally include nasoendoscopic instrumentation. Such evaluation is important, because velopharyngeal function may deteriorate after maxillary Le Fort I osteotomy with advancement (see Chapter 8). Velopharyngeal closure that was adequate before surgery may become borderline afterward, and closure that was borderline may become inadequate. In the past, investigators have speculated that, if the distraction (DO) technique is used to advance the Le Fort I osteotomy, then velopharyngeal function will not deteriorate. However, clinical studies have now documented that velopharyngeal function will deteriorate in a similar fashion after Le Fort I advancement when either DO or standard techniques are used.[12,13,35,37,50,54,58,61,72,89,94] Articulatory distortions that result from the jaw discrepancy and malocclusion also are identified by the speech pathologist, and cause-and-effect relationships are determined. It is known that the successful orthodontic and surgical correction of crossbites, open bite, residual palatal fistulas, and negative overjet will generally correct the presenting articulation errors (see Chapter 8).

The otolaryngologist plays a role in the assessment of upper airway and middle ear function. Chronic nasal obstruction and sinusitis are frequent in the patient with a cleft palate. Mucous trapping may also be a problem after a pharyngeal flap procedure. If sleep apnea is suspected, an attended polysomnogram should be carried out (see Chapter 26). If intranasal procedures (i.e., septoplasty and inferior turbinate reduction) are needed to improve breathing, they should be simultaneously carried out in conjunction with orthognathic surgery (see Chapter 10).

Timing of Orthognathic Surgery

The correction of the jaw deformity associated with ICP is best carried out when the skeleton is mature and before the patient completes high school, if feasible. Maxillofacial growth is generally complete between the ages of 14 and 16 years in girls and between the ages of 16 and 18 years in boys. However, skeletal growth is variable, and it may be further clarified via the analysis of sequential cephalometric radiographs (see Chapter 17). Input from the patient and the family regarding the timing of surgery and the patient's functional needs (e.g., breathing, speech, chewing, swallowing, body image, self-esteem) are also important considerations.

As early as 1986, clinicians clarified through preliminary studies that, if jaw surgery is undertaken in the growing patient with a cleft palate patient, revision orthognathic

surgery will likely be required after skeletal maturity is reached.[95-98] More recently, other investigators have tested this theory by proceeding with Le Fort I osteotomy involving DO methods during the mixed dentition. Studies to date indicate that a Le Fort I osteotomy carried out during the mixed dentition, whether with a standard or a DO technique, results in limited or no further horizontal maxillary growth.[17,36,46,73,74] As the mandible continues to grow, an Angle Class III malocclusion recurs with the need for either additional Le Fort I advancement or mandibular set-back.

Residual Deformities in the Adolescent with Isolated Cleft Palate

The adolescent or adult patient with ICP who is referred for orthognathic evaluation will have an intact alveolar ridge and generally will have a full complement of teeth. However, these individuals may present with one or more of the following residual cleft-related problems (Figs. 34-1 through 34-9):

1. *Maxillary dysplasia.* When maxillary dysplasia occurs in the patient with ICP, it generally follows one of two patterns. The first and most frequently seen is horizontal maxillary retrusion, generally with a degree of vertical deficiency and often with clockwise rotation of the maxillary plane. The second pattern is vertical maxillary excess with a more limited degree of horizontal retrusion. The latter tends to occur in the presence of nasal obstruction with forced mouth breathing and an open-mouth posture, especially if a pharyngeal flap was placed during childhood (see Chapter 4).
2. *Residual oronasal (palatal) fistula.* There may be a residual midline palatal fistula located in the region between the incisive foramen and the soft palate. This is a residual defect that occurs after initial palate repair earlier in life.
3. *Residual bony defects.* The alveolus is not clefted, but residual bony defects of the hard palate are to be expected. The hard palate bony defects do not generally require grafting or reconstruction.
4. *Chin dysplasia.* The patient with ICP will frequently be a mouth breather with resulting open-mouth posture. The end result is often a vertically long and flat chin (i.e., a limited projection of the pogonion). If the Robin sequence was present at birth, a degree of microgenia will likely be a component of the deficiency (see Chapter 4).
5. *Mandibular dysplasia.* True mandibular prognathism in the patient with ICP is not common, but it may be seen more frequently among patients with certain ethnic backgrounds (e.g., Asian). A degree of mandibular retrognathism as a residual aspect of the Robin sequence is likely. This often occurs in combination with a degree of maxillary deficiency and clockwise rotation of the maxillomandibular complex. The occlusion may be satisfactory with orthodontic compensation; however, the maxillomandibular horizontal deficiency with clockwise rotation is aesthetically obvious, and it may also negatively affect the upper airway (see Ch. 26).
6. *Nasal obstruction and sinus blockage.* Obstructed breathing through the nose and intermittent sinusitis are frequent in the individual who is born with ICP. This may result from a combination of septal deviation and enlarged inferior turbinates. An in-place pharyngoplasty (e.g., a superiorly based flap, a sphincteroplasty) may also be a cause of partial nasopharyngeal obstruction. These findings will also predispose these patients to obstructive sleep apnea (see Chapter 26).
7. *Velopharyngeal dysfunction.* It has been documented that approximately 20% of individuals with a repaired cleft palate will demonstrate velopharyngeal insufficiency by the time that they are 5 years old. The adolescent with ICP who is arriving for the evaluation of a cleft jaw deformity may have a pharyngoplasty in place. The Le Fort I osteotomy with advancement is likely to improve the upper airway, but it may negatively affect velopharyngeal function (see Chapter 8).

Orthodontic Considerations in the Patient with Isolated Cleft Palate with a Jaw Deformity

A primary goal of presurgical orthodontic treatment in the teenager with an ICP jaw deformity is to eliminate all existing dental compensations. Instituting camouflage treatment is likely to jeopardize periodontal health, lead to dental relapse, and it may also cause root resorption (see Chapter 5).

Correcting incisors inclination eliminating crowding, spacing, and rotations are all important orthodontic considerations. The arch form objectives are to achieve a satisfactory occlusion at operation that can be detailed afterward. To eliminate dental compensations, extractions may be required. When maxillary hypoplasia with negative overjet results in posterior crossbites as a result of "pseudo" constriction, it is important to not orthodontically overexpand the arch width. In the patient with ICP patient as compared with the patient with unilateral or bilateral cleft lip and palate, treatment is simplified because the alveolus is intact (i.e., there are no alveolar clefts) and there is generally a full complement of teeth.

Immediate Presurgical Assessment

When approaching the time of surgery, updated records are obtained, including alginate impressions of the maxillary

and mandibular arches, a centric relation bite registration, a face-bow registration, and facial measurements. The patient's medical and dental records are reviewed, including radiographs; dental models; photographs of the face and the occlusion; and special studies. Decisions are made with regard to the preferred changes (i.e., repositioning) of the jaws and the precise millimeter distances and angles required in each jaw to achieve the desired result (see Chapter 12).[59,60] Analytic model planning is carried out on the articulated dental casts, and splints are constructed. The splints assist with the achievement of the precise occlusion and the preferred facial aesthetics that were determined preoperatively (see Chapter 13).

Orthognathic Surgical Approach for Isolated Cleft Palate

Evolution of Surgical Techniques

In general, the primary jaw deformity observed in the adolescent with ICP is maxillary hypoplasia or dysplasia as a result of the original cleft deformity and the subsequent surgical interventions.[31,32] The usual reconstructive procedure to consider is a Le Fort I maxillary osteotomy.[20,28,30,47,53,56,92] Obwegeser showed that a circumvestibular incision with the separation of the pterygoid maxillary sutures followed by down-fracture and the disimpaction of

the maxilla was not only possible but clinically relevant.[66-70] This allowed the maxilla to be moved in any direction, either as one unit or in segments. Obwegeser clarified that full mobilization of the down-fractured maxilla was essential to the achievement of an orthognathic correction on the operating room table and to the limiting of skeletal relapse over time. Bell and others validated the use of the Obwegeser Le Fort I technique to allow for adequate blood supply for routine satisfactory bone healing without aseptic necrosis or dental injury (see Chapter 2).[3,4,7,21-24]

Current Operative Technique

The surgical technique for management of the maxillary deformity involves a standard circumvestibular incision and Le Fort I osteotomy (see Chapter 15).[75-81,83,84] In the patient with ICP, the soft-tissue dissection may be difficult just before down-fracture as a result of the scarring of the nasal mucosa to the palatal tissue. There will be a need to sharply separate the oral and nasal layers completely during the down-fracture procedure. Note that this is not a contraindication to maxillary surgery but rather just a technical point. Care is taken to prevent the subperiosteal dissection (i.e., separation) of the palatal mucosa from the underlying hard palate, because this would compromise circulation to the down-fractured maxilla. Although it is of interest, the presence of a pharyngeal flap generally does not alter the surgical approach. This author has not found it necessary to section an in-place flap to accomplish the planned surgical objectives.

Residual palatal oronasal fistulas in the patient with ICP will be difficult to close simultaneously with the Le Fort I procedure; the elevation and transposition of palatal flaps are generally required to do so, and this would compromise the blood supply to the down-fractured maxilla. Interestingly, if a water-tight nasal side closure can be achieved through the down-fractures before the maxilla is fixed in its new location, then the residual palatal side mucosa separation will frequently heal by secondary intention. However, if a palatal fistula remains, it can be closed 6 months to 1 year after the orthognathic procedure, either with local palatal flaps or, if necessary, by using an anteriorly based dorsal tongue flap.[82]

The simultaneous management of secondary deformities frequently requires bilateral sagittal split osteotomies of the mandible and an oblique osteotomy of the chin. If removal of impacted wisdom teeth is recommended for long-term dental health this is accomplished at the same time. If septoplasty or inferior turbinate reduction or both are required to improve nasal airflow, then the procedures are also carried out simultaneously (see Chapter 10).

Clinical Management after Initial Surgical Healing

After surgery, cephalometric and Panorex radiographs and facial photographs are obtained at standard intervals. The orthodontic maintenance of the surgical result and the detailing of the occlusion are generally resumed after initial healing (i.e., 5 weeks after surgery). A seamless transition from the surgeon to the orthodontist for ongoing care is essential. Speech and velopharyngeal function maybe reassessed 3 months after surgery. If a pharyngeal flap, a revision pharyngoplasty, or final palatal fistula closure is required, this can be carried out 6 months after the orthognathic procedure.

Orthognathic Surgery for Isolated Cleft Palate: Review of Study

In a previously published study, we assessed initial and long-term skeletal stability after Le Fort I osteotomy in 14 skeletally mature patients with ICP who underwent palate repair during infancy and who then presented as adolescents with maxillary dysplasia and malocclusion.[83]

Patient and Methods

In a study by Posnick and colleagues, the medical records, longitudinal cephalometric radiographs, and current clinical examinations of all patients with ICP who underwent Le Fort I osteotomy over a 3-year period by a single surgeon (Posnick) were reviewed.[83] The following information was noted: all previous cleft and maxillofacial surgical procedures; stabilization techniques; the presence of a pharyngoplasty; the use of a bone graft; perioperative orthodontics; age at surgery; perioperative morbidity; and, at final follow up, the amount of overjet and overbite of the incisors. All patients were skeletally mature at the time of the operation. In all patients, lateral cephalograms were taken before surgery and at 3 to 7 days, 6 to 8 weeks, and 1 year postoperatively.

On each preoperative radiograph, the facial plane was constructed for each patient. At the level of the palatal plane, a perpendicular plane was constructed to form a Cartesian coordinate system that was referenced for skeletal measurements. The serial radiographs taken after surgery were superimposed on the anterior cranial base structures with the Cartesian coordinate axes as planes of reference. Vertical and horizontal directional changes were then measured at each postoperative interval. With the radiographs superimposed, the amount of horizontal advancement was measured by the method of anatomic best fit. Vertical change over time was analyzed anteriorly at the incisor area and posteriorly at the first molar area. Actual measurements could be determined reliably within 0.5 mm. The 1-year postoperative lateral cephalograms also were assessed for the measurement of incisor overjet and overbite.

Differences between groups were assessed by Student's *t*-test. Associations between the magnitude of surgical advancement and the degree of relapse were examined by the Pearson correlation coefficient (r) and by least-squares linear regression analysis. Correlations were considered significant when the P value was less than .05.

All patients underwent a standard one-piece Le Fort I osteotomy extended through the zygomatic buttress (i.e., below the malar eminence) and anteriorly into the pyriform apertures. After titanium mini-plates were used to rigidly fix the osteotomy in place, crafted corticocancellous iliac bone grafts were wedged between the zygomatic buttress and the pyriform aperture on each side and secured with an additional micro-plate and screws. Simultaneous bilateral sagittal split ramus osteotomies were used in 4 of 14 patients to manage secondary deformities. All subjects underwent a simultaneous osseous genioplasty. In all patients, the prefabricated splint secured to the maxillary orthodontic brackets confirmation that the occlusion remained unchanged for 5 weeks.

The age at operation ranged from 17 to 25 years (mean, 19 years). During the study period, the ICP patients (N = 14) represented just 12% of the surgeon's patients with cleft lips and palates who underwent orthognathic surgery. All study patients had a complete set of longitudinal records (clinical and cephalometric) and were available for late postoperative clinical reassessment. Clinical follow up ranged from 1.5 to 5.5 years (mean, 2.5 years) after surgery at the close of the study.

Results

Perioperative morbidity was unremarkable when patients were reviewed for cardiopulmonary compromise, maxillofacial infections, hemorrhage, aseptic necrosis, loss of teeth, or the need for root canal therapy. All patients maintained a positive overjet and overbite at the incisor level, which was documented on both the 1-year clinical and cephalometric examinations. No significant difference was seen in vertical or horizontal surgical change or in postoperative relapse between those who had Le Fort I osteotomy only (n = 10) and those who underwent simultaneous Le Fort I and bilateral sagittal split ramus osteotomies of the mandible (n = 4) or between those who underwent iliac bone grafts (n = 10) and those who did not (n = 4). With reference to these variables, the patients were therefore considered a homogeneous group for the purposes of further analysis.

As measured directly from the serial cephalometric radiographs for each patient, the mean horizontal advancement achieved was 6.4 mm, and 5.4 mm of advancement was maintained at 1 year. Three of the 14 patients showed no more than 0.5 mm of relapse, and none had more than 1.5 mm of relapse. In the eight patients without a pharyngoplasty in place at the time of Le Fort I osteotomy, the horizontal advancement was 6.1 mm immediately after the operation and 5.1 mm 1 year later. The remaining six patients achieved a similar horizontal advancement both immediately after the operation (6.9 mm) and 1 year later (5.9 mm).

The vertical change that was achieved initially and then maintained over the long term was analyzed in both the anterior and posterior regions of the upper jaw to assess regional differences in skeletal ability patterns more accurately. The mean anterior vertical change of the maxilla was 2.0 mm immediately after the operation and 1.4 mm after 1 year. The mean posterior vertical change of the maxilla was 2.7 mm immediately after the operation and 1.9 mm after 1 year (mean relapse, 0.8 mm).

Controversies and Unresolved Issues

Skeletal Stability after Le Fort I Osteotomy

The study by Posnick and Taylor assessed the skeletal stability and relapse patterns in mature adolescents and young adults with ICP who underwent palate repair during infancy and who later developed maxillary dysplasia that required orthognathic surgery for the improvement of facial balance, the airway and the occlusion.[83] Interestingly, the skeletal stability in the patients with ICP after Le Fort I osteotomy was somewhat better than that documented in patients with unilateral cleft lip and palate. Posnick and Taylor's study confirm that an in-place pharyngoplasty does not contribute to relapse or increase perioperative morbidity. Roughly half the measured horizontal and vertical relapse occurred during the first 6 weeks after the operation, and the remainder occurred during the rest of the first year. A long-term positive overjet and overbite was maintained in all patients.

The Standard Approach versus the Distraction Approach to Le Fort I Advancement

The use of a DO technique to reposition the maxilla gradually over several weeks into the preferred horizontal position and to then hold the maxilla in place with the DO appliance for several months during the consolidation phase is relatively inconvenient and costly to the patient, the family, and the health care system. It remains a distant second choice as compared with the standard approach when the surgeon is able to down-fracture the maxilla, adequately mobilize it, and then place it into the preferred position in the operating room. The standard approach originally described by Obwegeser during the 1960s and then continually refined offers a safe and effective way to manage most jaw deformities that occur in the patient with ICP.[66-70] Despite two decades of use, the DO technique for maxillary advancement has not been shown to offer less morbidity or improved stability for the patient with a cleft jaw deformity.* It does not allow for the correction of the deformity during childhood, as many clinicians had initially hoped it would. No horizontal growth can be expected after a Le Fort I osteotomy is carried out, whether with a DO approach or a standard appro ach.[17,36,46,73,74,95-98] The DO approach has not diminished the occasional occurrence of velopharyngeal insufficiency after Le Fort I osteotomy, and it has not eliminated the problem of skeletal relapse.[12,13,35,37,50,54,58,61,72,89,94] Alternatively, the DO approach is useful in unusual circumstances, when the surgeon is not able to adequately mobilize and fully advance the maxilla as planned in the operating room. For patients

*References 1, 2, 8, 9, 15, 16, 25, 26, 29, 38, 39, 40-45, 48, 49, 52, 57, 63, 78, 83, 84, 88, 93

of special concern, the surgeon may wish to discuss the DO option before the Le Fort I advancement occurs. If the surgeon is unable to sufficiently mobilize and reposition the maxilla with the use of standard techniques, then a DO appliance can be placed (see Chapter 32).

Closure of Large Residual Palatal Fistula

When a recalcitrant large oronasal fistula at the incisal foramen region remains in a patient with ICP, palatal flaps alone may not be adequate for closure. In these cases, options are limited. This author often suggests achieving nasal side closure with the use of local full-thickness palatal (turnover) flaps and then obtaining oral side closure by elevating and placing an anteriorly based dorsal tongue flap. The tongue flap will provide needed vascularized soft tissue for effective fistula closure on the oral side.[82] This approach does require the sacrifice of a small portion of the tongue donor site, a second general anesthetic, and downtime for the patient during the initial convalescence period (see Figure 34-4 and 34-5).

Conclusions

Patients with ICP present varied dental, occlusal, upper airway, middle ear, speech-related, and aesthetic needs throughout their childhood, adolescent, and adult years. At least 20% of these patients who undergo palate repair during infancy will develop maxillary dysplasia that is not responsive to orthodontic treatment alone. An integrated comprehensive surgical–orthodontic approach is required to resolve these problems at the time of skeletal maturity. When indicated, a Le Fort I osteotomy in combination with mandibular, chin, and intranasal procedures represents the standard of care for the establishment of improved facial balance, occlusion and dental rehabilitation, and breathing.

Management of Secondary Jaw Deformities after Maxillofacial Trauma

JEFFREY C. POSNICK, DMD, MD

- Posttraumatic Temporomandibular Joint Ankylosis in the Pediatric Population
- Posttraumatic Saddle-Nose Deformity
- Posttraumatic Orthognathic Deformities
- Posttraumatic Segmental Dentoalveolar Defects
- Conclusions

Despite the best of intentions by the primary trauma team, a subgroup of individuals who sustain facial injuries later present with deformities that require secondary reconstruction. The initial evaluation and resuscitation of the individual who has sustained craniomaxillofacial trauma is similar to that of patients with other organ system injuries. At times, the patient's general health and other body region injuries are likely to take precedence over the management of any facial fracture. In addition, there are treatment options to consider for each craniomaxillofacial fracture, and judgment is required to select the approach that is most likely to result in a favorable outcome: open versus closed reduction; method of fixation; grafting requirements; immediate or delayed dental treatment; and the management of associated soft-tissue injuries. Treatment is individualized to accommodate the healing of each fracture and to simultaneously consider cerebral function, vision, breathing, chewing, swallowing, speech, the cervical spine, and temporomandibular joint (TMJ) injuries and to maintain cardiovascular health. Another factor is the residual facial growth requirements in a child who sustains an injury and who has not yet reached skeletal maturity. If the injured and repaired craniomaxillofacial bones do not grow normally, secondary deformities result over time. For all of these reasons, secondary deformities after facial skeletal injury (with or without effective primary repair) may occur and require later reconstruction. Specific patterns of secondary maxillofacial deformities are seen with enough frequency that each is reviewed separately.

Posttraumatic Temporomandibular Joint Ankylosis in the Pediatric Population

Background

The treatment of TMJ ankylosis poses challenges to the maxillofacial surgeon as a result of technical difficulties associated with access to the joint, the currently available autogenous and prosthetic TMJ replacement options, and the high incidence of ankylosis recurrence. Failure to restore adequate mandibular opening is likely to result in speech and swallowing impairment; difficulty with mastication; poor oral hygiene and dental neglect; continued facial growth disturbances; and the potential for airway compromise. The surgical management of bony ankylosis of the TMJ requires the complete excision of the involved osseous mass with intraoperative achievement of satisfactory passive mouth opening. The immediate reconstruction with a costochondral rib graft is often carried out, and this is followed by a postoperative physiotherapy regimen to maintain mouth opening. A number of authors have critically evaluated the treatment of TMJ ankylosis in adults, with less emphasis placed on addressing this problem exclusively in the pediatric population.*

In a study by Posnick and colleagues, a consecutive series of nine pediatric patients (mean age, 7.7 years) who underwent a standardized treatment protocol for 13 affected ankylosed temporomandibular joints was reviewed.[88] Four patients had unilateral TMJ ankylosis, and five had bilateral ankylosis. One child required bilateral release but only unilateral reconstruction. Radiographic evidence demonstrated bony ankylosis in all 13 operated joints. Two patients had

*References 1, 3-6, 8, 12, 13, 16-19, 34, 36, 41, 42, 44-47, 56, 57, 59, 61, 62, 67, 68, 71, 73, 76, 78-81, 87, 88, 96, 98-100, 102-104, 116, 119, 120, 122, 123

previously undergone surgical intervention of the TMJ. The cause of ankylosis within the study group was primarily traumatic or congenital. The protocol that was followed included complete excision of the involved ankylotic structures with mobilization through coronal scalp and Risdon neck incisions as well as the achievement of wide mouth opening. This was followed by immediate costochondral grafting. Fixation with mini-plates and screws allowed for early mobilization with the rapid institution of a physiotherapy program (Fig. 35-1).

For the study patients, despite the achievement of full passive mouth opening in the operating room, less long-term success was realized. Those with unilateral TMJ ankylosis maintained the best long-term vertical opening. On average, they went from 5 mm of maximum vertical opening (separation of the incisors) before surgery to 25 mm of active range of motion maintained for the long term. For patients with bilateral TMJ ankylosis, the maximum long-term incisal opening was only 18 mm. Mean follow-up duration at the close of the study was 2 years. Perioperative complications were minimal, with no evidence of infection, facial nerve injuries, or need for transfusion. In general, patients with unilateral or bilateral ankylosis of traumatic cause achieved satisfactory functional results after surgery, whereas those in the bilateral congenital TMJ ankylosis group attained results that were far more limited. This likely represents limitations in the intrinsic neuromotor function of the congenital cases.

Controversies and Unresolved Issues

Knowing the cause of TMJ ankylosis helps with the understanding of its pathophysiology. In developed countries, the most common etiology is trauma, followed by infection.[33,48,121,125,126] Topazian found an association with trauma in 39% and with infection in 43% of patients with TMJ ankylosis (N = 229).[119] Since the late 1970s, authors have found trauma to be a more frequent cause than infection, probably because of the use of antibiotics to combat the latter. In a report of a series of patients with TMJ ankylosis, Rajgopal and colleagues concluded that 80% of cases were traumatic in origin.[96] Unfortunately, these reviews lumped both pediatric and adult patients together.

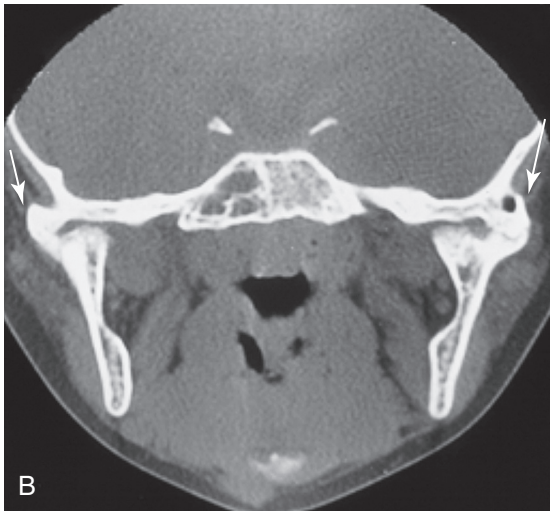
Surgical attempts to release TMJ ankylosis have been described dating back to 1850.[5] Since then, ankylosis release followed by reconstruction using a variety of alloplastic and autogenous materials has been repoted.[9,15,34,46,50,53,62,68,72,79,81,101,114,124,129] Although Gillies first described costochondral grafting for TMJ reconstruction in 1920,[30] it was Poswillo[93,94] and MacIntosh and Henny[53] who popularized its use during the 1970s. Poswillo attempted to demonstrate the histologic and physiologic similarities between the mandibular condyle and rib cartilage in humans.[93] MacIntosh and Henny described 26 cases of costochondral grafting for mandibular condyle replacement, with 6 of them being for ankylosis.[53] Their approach included graft stabilization with interosseous wires and intermaxillary fixation (IMF) for 6 to 8 weeks. They claimed subsequent growth of the grafts in their pediatric patients, but they failed to provide any objective data.

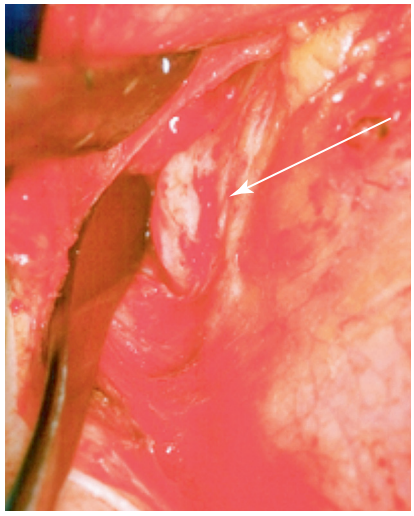
In 1973, Kennett reported on two cases of unilateral TMJ ankylosis in young patients who underwent the combination of condylectomy, coronoidectomy, and reconstruction with a wired rib graft.[45] He concluded that ankylosis in children should be treated as soon as possible and that recurrence is the most frequent complication. In 1986, Munro and colleagues reviewed their series of 18 adult and pediatric patients with TMJ ankylosis and facial deformity.[67] Their reconstruction included interosseous wiring of the rib graft and 8 weeks of IMF followed by physiotherapy. They demonstrated better results in unilateral ankylosis cases than in bilateral cases. The next year, Lindqvist and associates described 27 patients of varying ages with TMJ ankylosis; 25 of them underwent costochondral graft reconstruction. Fixation was also by direct interosseous wires, but IMF was reduced to 3.5 weeks to encourage early mobilization and to limit recurrence. The maximum incisor opening improved from 16 mm to 31 mm. In 1987, Politis and others reported satisfactory results in six patients (five adults) with ankylosis.[81] They employed a preauricular approach that involved the use of costochondral grafts and either wire or plate and screw fixation followed by 2 or 6 weeks of IMF, respectively. However, 50% of their patients developed seventh cranial nerve palsies. In 1990, Kaban and colleagues described their experience in 14 adult and pediatric patients with TMJ ankylosis and indicated satisfactory results.[41,42] The protocol reported by Posnick and colleagues was similar to that of Kaban and colleagues except that the former found that the use of a mini-plate with screw fixation improved stability (as compared with interosseous wire fixation), thereby allowing for the minimal use of IMF and the early initiation of mandibular range of motion with active physiotherapy.[88]

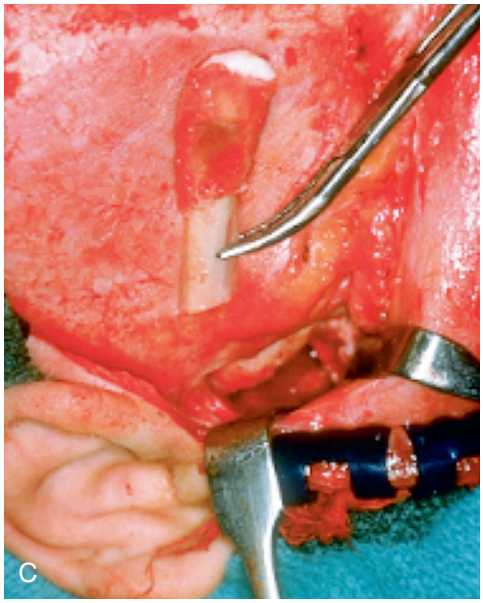
In 2009, Kaban and colleagues described an updated protocol for the management of TMJ ankylosis exclusively in children.[78,79,122,123] They restated their observation that the most common cause of treatment failure was inadequate resection of the ankylotic mass followed by the failure to achieve adequate passive maximum opening in the operating room. Clearly, unless adequate passive mandibular vertical opening is achieved in the operating room, failure will inevitably occur. Unfortunately, this is no guarantee that mouth opening will be maintained. Their seven-step protocol consisted of the following:

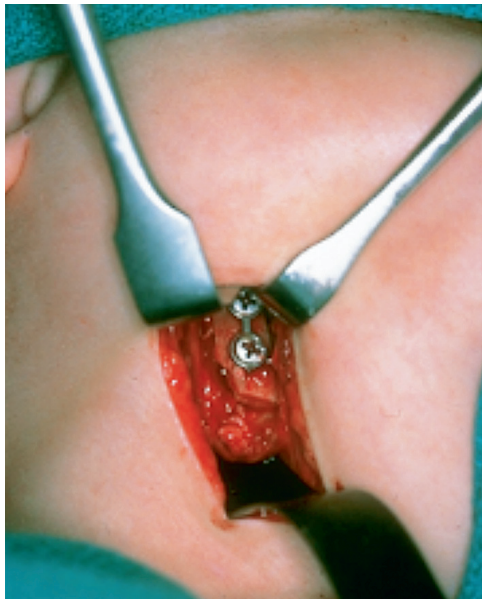
1. Complete excision of the fibrous and/or bony ankylotic mass
2. Coronoidectomy of the affected side
3. Coronoidectomy of the contralateral side if steps 1 and 2 do not result in a maximum incisal opening (>35 mm) or opening to the point of dislocation of the unaffected TMJ
4. Lining of the TMJ with either a temporalis myofascial flap or the native disc, if it can be salvaged

Bony ankylosis



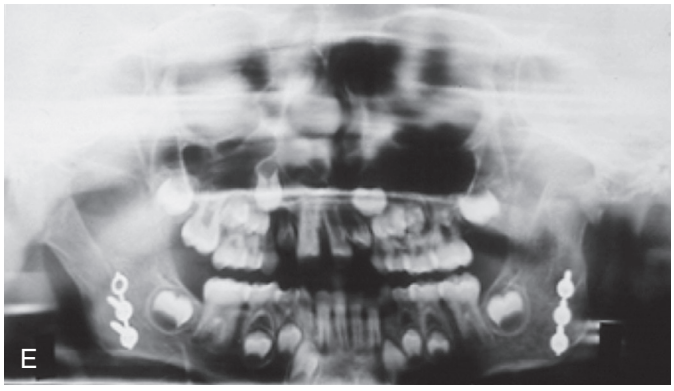


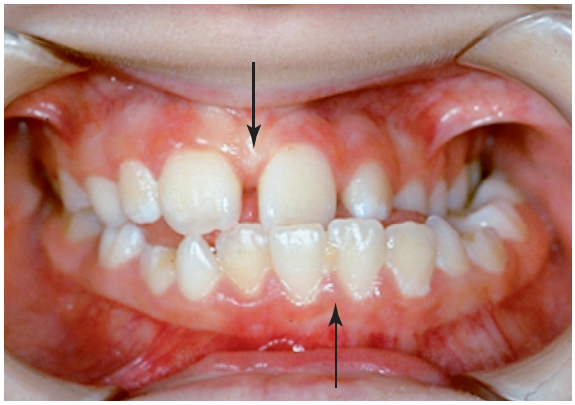




• **Figure 35-1** A 5-year-old girl was referred to this surgeon after intracapsular condyle fractures of the mandible resulted in bilateral temporomandibular joint ankylosis. These fractures were unrecognized and went untreated at the time of injury 1 year earlier. **A,** Preoperative frontal views showing maximal opening limited to 4 mm. **B,** Preoperative computed tomography scan that demonstrates the bony ankylosis of each condyle to its zygomatic arch. Intraoperative view demonstrates ankylosis to the zygomatic arch to the condyle as viewed through the coronal scalp incision. **C,** Intraoperative view of costochondral graft placement through the coronal scalp incision. Stabilization of the rib graft through Risdon neck incision with the use of a mini-plate and screws.

Continued





• **Figure 35-1, cont'd** **D,** Facial views 1 year after reconstruction showing good cranial nerve VII function and satisfactory vertical mouth opening being maintained. **E,** Postoperative Panorex and anteroposterior facial radiographs. **F,** Facial view with maximum mouth opening maintained 3 years after reconstruction but with asymmetrical overgrowth of the costochondral grafts. Occlusal view 3 years after reconstruction that shows an asymmetrical Angle class III malocclusion as a result of the overgrowth.

5. Reconstruction of the ramus condyle unit with either proximal segment osteotomy and distraction osteogenesis or costochondral graft and plate and screw fixation
6. Early mobilization of the jaws: If distraction osteogenesis is used to reconstruct the ramus condyle unit, mobilization begins the day of operation. In patients who are undergoing costochondral graft reconstruction, mobilization begins after 10 days of IMF.
7. All patients receive rigorous physiotherapy after surgery to maintain mouth opening, generally for at least 3 to 6 months

Observations and Recommendations

Several generalizations can be made about pediatric patients with TMJ ankylosis. *First,* in first-world countries as in the adult population, trauma remains a prevalent cause, and this is followed closely by congenital issues. In underdeveloped countries, infection continues to be an important causative factor.[92] *Second,* although patients with unilateral ankylosis present with a severely limited preoperative opening, they are more likely to achieve satisfactory long-term functional results. *Third,* children with bilateral congenital TMJ ankylosis generally attain poor long-term results, despite adequate intraoperative release. This is likely the result of associated masticatory muscle anomalies, neuromuscular discoordination, or longstanding muscular disuse atrophy. *Fourth,* the use of mini-plate and screw fixation of the graft diminishes the need for immobilization, thereby allowing for the early institution of physiotherapy. Unfortunately, this does not guarantee the maintenance of a satisfactory long-term opening. *Fifth,* when a costochondral graft is used in children, only several millimeters of cartilage should remain. This is to limit the frequent complication of overgrowth and its complex secondary deformities. In clinical practice, overgrowth after costochondral grafting remains a frequent occurrence (see Chapter 28 and Fig. 35-1). *Sixth,* for most patients, reconstruction to achieve long-term maxillomandibular harmony must wait until they have achieved skeletal maturity (i.e., 14 to 18 years of age).

Posttraumatic Saddle-Nose Deformity

Background

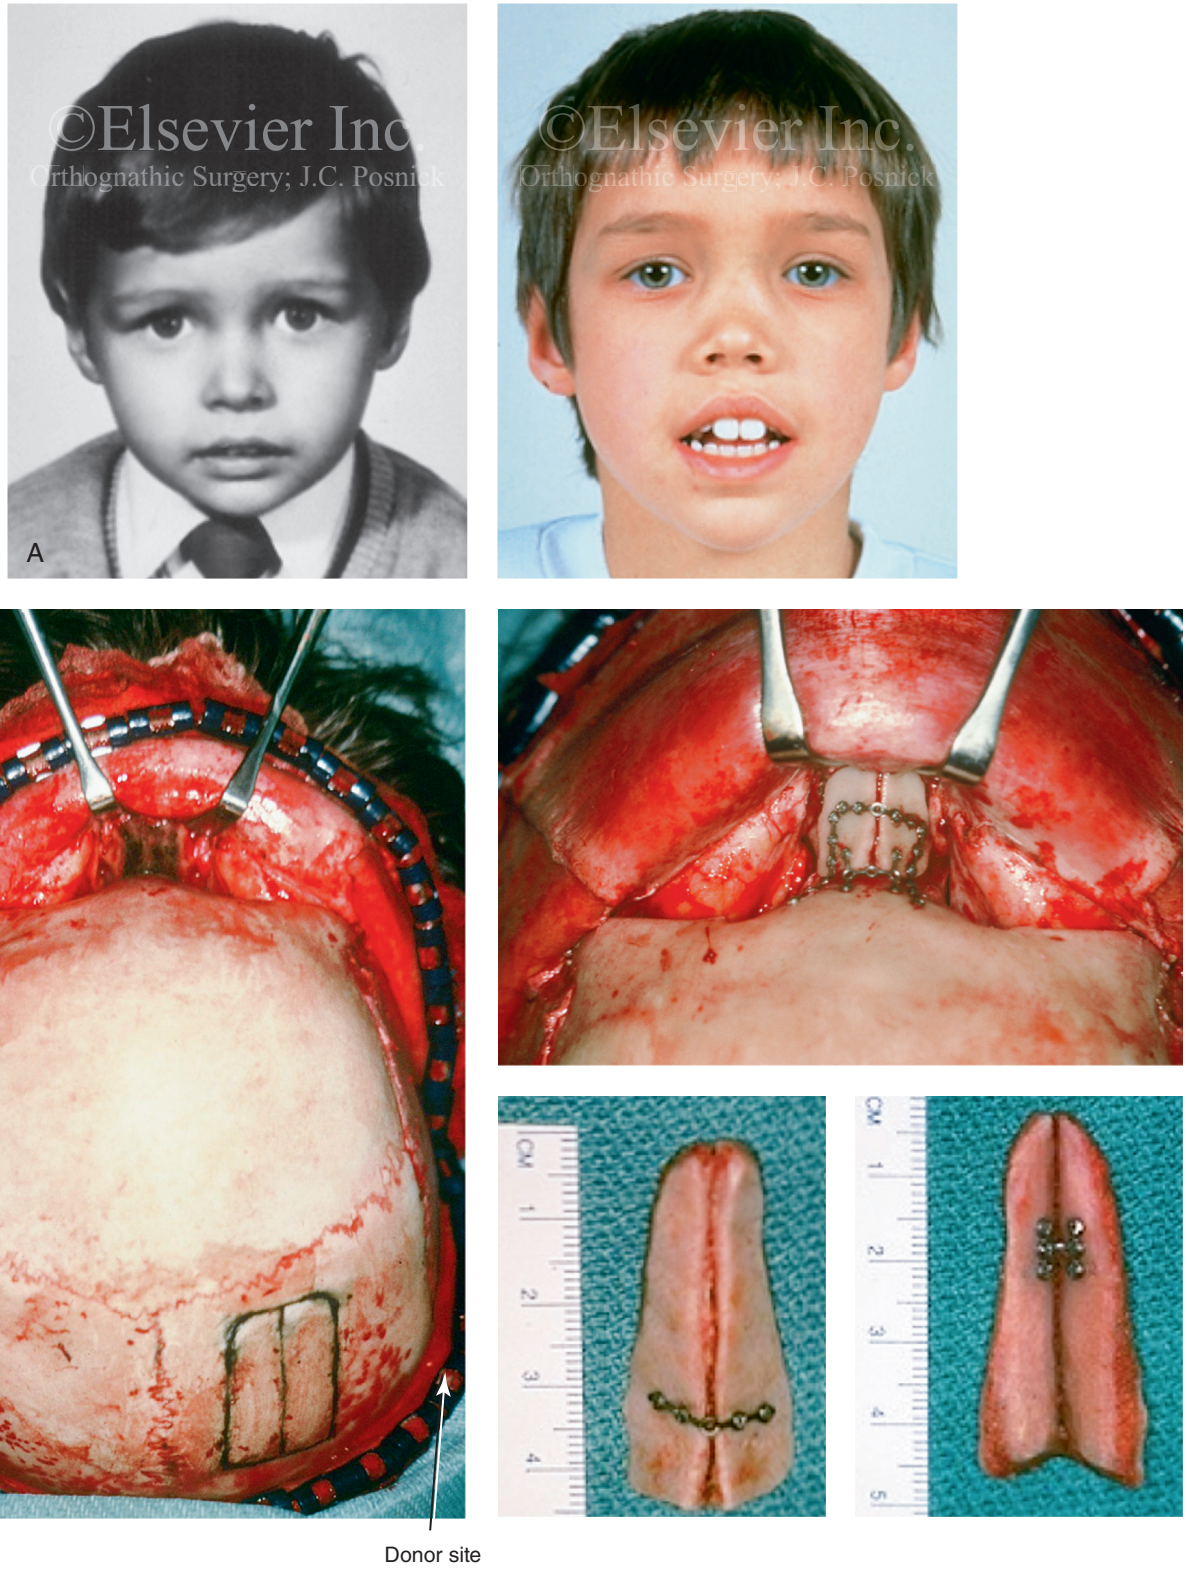
Nasal injuries are often recognized but then ignored as being unimportant.[11,82,86] When a depressed nasal fracture occurs in a child, injury to the growth center leaves the nose prone to a so-called "saddle deformity" with flattening of the osseocartilaginous vault.[63] In general, the overlying soft tissues, the upper and lower lateral cartilages, and the nasal lining are distorted but remain intact. Reconstruction of a saddle deformity that involves the bony and cartilaginous dorsum is generally carried out with an autogenous graft (e.g., chondral, costochondral, iliac, split- or full-thickness cranial) (Fig. 35-2).[27,28,32,38,60,74,91,117,118,131] The use of an allogenic graft (e.g., porous polypropylene) is always a second choice as a result of a higher incidence of associated infection and extrusion.[43] The type of graft material selected (e.g., bone, cartilage, allograft), the method of fixation, the incisions required for access, the extent of dorsum that requires reconstruction, and the timing of treatment are all important details and will vary according to the age of the patient, the extent of the deformity, and the surgeon's personal preferences (see Chapter 38).

Involvement of Both the Bone and the Cartilage Vault

The autogenous graft used (e.g., chondral, costochondral, rib, iliac, split- or full-thickness cranial) is contoured to provide reasonable nasal dorsum morphology. When the whole dorsum requires reconstruction (i.e., the radix to the nasal tip), the lower lateral cartilages are sutured over the top of the graft to provide a more natural tip contour and feel (see Fig. 35-2). When a bone graft extends from the radix to the tip, minor degrees of graft resorption at the tip should be anticipated. When correcting the saddle deformity with bone graft, freshening the base of the nasal bones with a rotary drill before graft placement is carried out; the onlay graft will then rest on a bleeding base. The accurately shaped graft is either dovetailed into a bony groove at the nasofrontal process or abutted to the frontal bones while resting evenly on the contoured and freshened) dorsal base to establish the correct nasofrontal angle. Stabilization of the bone graft is either with microplates and screws or transcutaneous Kirschner wires, depending on the access provided by the incisions that are used for the reconstruction. If a coronal scalp incision or a direct vertical nasal incision is used, plate and screw fixation is easily accommodated. An open approach (i.e., a columella splitting incision) should be combined when a coronal scalp incision is used to best manage the lower lateral cartilages and the nasal tip (see Chapter 38 and Fig. 35-2).

Involvement of the Cartilage Vault Only

When the saddle deformity causes collapse of the septal cartilage without injury to the nasal bones, then a cartilage graft reconstruction is preferred. A rib cartilage dorsal strut graft is crafted and placed flush with the nasal bones. The graft then extends caudal to the tip. The tip of the dorsal strut graft is joined to a second rib cartilage graft (caudal strut) that extends from the base of the maxilla to the nasal tip. The caudal strut is stabilized with a short buried Kirschner wire (no. 35 threaded) that is secured to the base of the maxilla/anterior nasal spine region and then pierced into the graft (Fig. 35-3). There is no advantage to harvesting the L-shaped rib cartilage graft as one unit. The separately crafted dorsal strut and caudal strut grafts are then joined together at the tip with non-resorbable suture. The lower lateral cartilages are sutured together and over the



• **Figure 35-2** A 4-year-old boy fell and hit the bridge of his nose on a hard tabletop, which resulted in a saddle-nose deformity (i.e. osseous and cartilagenous vault). He arrived for evaluation when he was 8 years old and then underwent reconstruction through a coronal scalp incision with nasal osteotomies (in-fracture) and the placement of fixed crafted full-thickness cranial grafts. **A,** Frontal view at 3 years of age just before injury and at 8 years of age just before surgery. **B,** Intraoperative views through the coronal scalp incision that show the frontonasal region and the proposed right calvarial donor site. Crafted full-thickness cranial bone grafts are shown before placement for nasal reconstruction. Stabilization is achieved with microplates and screws. A close-up view of the frontonasal region shows the full-thickness cranial bone grafts in place and stabilized with microplates and screws.

grafts to form the new nasal tip. This technique is efficient and results in a "soft" nasal tip that looks and feels natural (see Chapter 38).

Posttraumatic Orthognathic Deformities

Background

At times, the resuscitation of the trauma patient may lead to incomplete preoperative imaging and evaluation and the rushed treatment of the associated maxillofacial injuries. At other times, the primary facial fracture management is delayed by injury of multiple systems. If so, the incidence of infection, malunion, or non-union that results in secondary deformities and malocclusion is increased. In severely traumatized patients, neurologic injuries are often the main concern, especially during the first days of observation. Maxillofacial injuries may be neglected and the status of the occlusion not properly evaluated as a result of the need for orotracheal intubation, masticatory muscle spasm, difficulty assessing a comatose or uncooperative patient, or the lack of availability of a maxillofacial specialist. There may also be associated dental trauma (e.g., fracture or avulsion of

• **Figure 35-3** A middle-aged woman of Arabic origin with a postsurgical (iatrogenic) saddle-nose deformity. Two years earlier, she underwent an aggressive septoplasty procedure at another institution. This resulted in a large septal perforation with collapse of the cartilaginous vault. She arrived for evaluation and then underwent nasal reconstruction that included rib cartilage grafting (caudal and dorsal struts). **A,** Frontal views before and after reconstruction. **B,** Left oblique view before and after reconstruction. **C,** Profile view before and after reconstruction. **D,** Computed tomography scan views (coronal cut) of nasal septum confirming the extent of the septal deficits before reconstruction.

the teeth) that was not recognized, neglected, or managed unfavorably in a hospital setting without available dental expertise.

Posttraumatic secondary maxillomandibular deformities may occur as a result of inadequate initial anatomic reduction or stabilization and fixation of a jaw fracture or the late resorption and remodeling of the bones resulting in malunion.[23-25,35,101,105,111,115,132] The segmental loss of maxillary or mandibular dentoalveolar components may also have occurred, as discussed later in this chapter. In the child, limited growth of the bones after the initial injury (e.g., condylar fracture) or as a result of the surgical intervention carried out to reduce and stabilize the fracture may also cause secondary deformities.[58,108,113]

There are patterns of posttraumatic orthognathic deformities that occur with enough regularity that they are reviewed separately in the following sections of this chapter.

Malunion after Midface (Le Fort I) Fracture

An elongated face with an anterior open-bite malocclusion (counterclockwise rotated maxilla and clockwise rotated mandible) can occur when a Le Fort fracture is allowed to heal with inadequate reduction or stabilization at the time of initial management.[30,40,87,132] The displaced maxilla often heals inferiorly with counterclockwise rotation. The mandible is forced into a clockwise-rotated position that involves a retrusive pogonion seen in profile. Another common reason for malocclusion after midface fracture is an unrecognized palatal split with secondary arch-form deformity.[25,132] Reconstruction requires osteotomies to recreate the midface fractures followed by the surgical repositioning of the maxilla into the correct (preinjury) anatomic location. The uninjured mandible will then counterclockwise rotate to close the anterior open bite, to improve the horizontal projection at the pogonion, and to reduce the vertical height of the lower face.[43,87] Another frequent scenario is when a midface fracture occurs during childhood and then results in growth disturbance. At the time of facial growth maturity (i.e., 14 to 18 years of age), maxillary hypoplasia with a skeletal class III malocclusion will be evident (Fig. 35-4).

Late Secondary Consequences of a Condylar Fracture

There are many published opposing treatment protocols for the primary management of mandibular condyle fractures.[2,10,21,22,31,59,63-66,112,127,133] Despite much discussion, controversy remains regarding which type of condyle fracture should be treated open rather than closed and, if operated, what approach (i.e., incisions for access, extent of condylar fragment degloving, method of fixation, postoperative immobilization and remobilization protocol) is optimal for each specific fracture. In addition, when a condyle injury or fracture occurs in a child, it can easily be overlooked or misdiagnosed, especially if the individual has no other apparent injuries. The child may not even arrive for evaluation; if evaluation does occur, the patient may be seen by a general practitioner rather than a specialist. Radiographs may be limited as a result of the need for sedation or concern by the parents about ionized radiation exposure.[49,83,84]

Regardless of the primary treatment rendered, a frequently seen pattern of late secondary deformity results when the condylar injury occurs prior the completion of mandibular growth (Figs. 35-5 through 35-10).[26,29,69,83-85,87,89,90,95,109,110] Often there is asymmetrical growth of the mandible from that point forward, with ipsilateral mandibular hypoplasia (see Chapter 4). Canting of the mandible (up on the ipsilateral side), shift of the dental midline (toward the fracture), and malocclusion (ipsilateral Class II) are frequently seen. The upper jaw is secondarily affected, growing with vertical asymmetry (canting) and with a shift of the maxillary dental midline toward the side of the fracture.

When facial growth is complete, orthodontic alignment to eliminate dental compensations in combination with orthognathic surgery (Le Fort I osteotomy, sagittal ramus osteotomies of the mandible, and osseous genioplasty) will allow three-dimensional repositioning of the jaws to improve facial symmetry, to restore Euclidian proportions, and to correct the malocclusion (see Figs. 35-5 and 35-7). This classic posttraumatic dentofacial deformity and orthognathic approach to reconstruction assumes a stable posterior stop when seating the ipsilateral condyle, adequate mouth opening, and minimal TMD.

Orthognathic surgery is not preferred for patients with significant mandibular hypomobility. Limited mouth opening makes intraoral surgery difficult; in some cases, it may worsen when the cicatricial effects of a surgical wound are added.[14,20,70,77,106] If feasible, the hypomobility is resolved before the jaw deformity is definitively addressed (see Fig. 35-9).

When considering the timing of orthognathic surgery for a patient after a condyle fracture, another essential aspect is to wait until the temporomandibular articulation has stabilized. Becking and colleagues reported stable orthognathic results in their patients who had sustained displaced condylar fracture with a loss of posterior facial height.[3] They postponed definitive orthognathic treatment until at least 9 months after the initial injury. In clinical practice, each of these patients should be considered individually with regard to the stability of the temporomandibular articulation. In general, I like to allow 6 months of healing before proceeding with definitive reconstruction (see Fig. 35-10). Unfortunately, no one test or radiographic study can reliably answer the question of condylar stability (see Chapter 4).

When a condylar neck fracture heals with resorption of the entire proximal condylar fragment, not only is there significant loss of ipsilateral posterior facial height but there is also an unstable posterior stop. Correction will require the construction of a neocondyle.[15,37,114,124,128,129] In this case, as long as there is satisfactory mouth opening, use a costochondral graft for reconstruction is preferred (see

• **Figure 35-9** When she was 16 years of age, this patient fell from a height of 6 meters and sustained maxillofacial and lower extremity trauma. Her maxillofacial injuries included a displaced left condyle fracture, a displaced right condyle fracture, a comminuted left anterior mandibular fracture with the loss of teeth, and left anterior maxillary dentoalveolar fractures. She was treated at another institution with tracheostomy, open reduction and internal fixation of the comminuted anterior mandibular fractures, debridement of the anterior maxilla and the associated teeth, and closed reduction of the bilateral condyle fractures. The lower extremity fractures required the placement of left and right femoral rods and open reduction and internal fixation of the right ankle and foot fractures. The patient underwent several months of intermaxillary fixation. With the release of the fixation, radiographs confirmed bilateral temporomandibular joint (TMJ) ankylosis. One year later, the patient was taken to the operating room for the removal of the internal fixation of the left anterior mandible.

She was referred to this surgeon when she was 20 years old for secondary reconstruction. She was found to have bilateral TMJ ankylosis, malunion and displacement of the mandible, anterior maxillary dentoalveolar defects, the loss of multiple teeth in both arches, and impacted wisdom teeth. She underwent a comprehensive assessment that also included the evaluation of her dental rehabilitative needs. An orthodontist and a prosthodontist were consulted, and perioperative orthodontic treatment was instituted. **A,** Frontal views in repose before and after reconstruction and dental rehabilitation. **B,** Frontal views with smile before and after reconstruction and dental rehabilitation.

• **Figure 35-9, cont'd** Staged maxillofacial reconstruction included the following:

1. Left and right TMJ ankylosis release, including left and right coronoidectomies with the immediate improved mandibular range of motion
2. Six months later, maxillomandibular reconstruction that included:
   - Bilateral sagittal split ramus osteotomies
   - Harvesting of anterior iliac crest graft
   - Oblique osteotomy of the chin
   - Reconstruction of the anterior maxillary defect with autogenous corticocancellous bloc graft
   - Revision of the tracheostomy scar
3. Six months later, a left parasymphyseal osteotomy and a right sagittal split ramus osteotomy to further improve the mandibular arch form

Six months after successful bloc grafting to the anterior maxilla, four dental implants were placed. Six months after successful implant placement, restorative dentistry was carried out that included crown and bridge work in both arches. **C,** Profile facial views before and after reconstruction and dental rehabilitation. **D,** Oblique facial views before and after reconstruction and dental rehabilitation.

• **Figure 35-10, cont'd** This further altered the occlusion and involved a shift of the mandible to the left and a step-off between the right central and lateral incisors. The fractures were treated with the placement of surgical arch wires; open reduction and internal fixation of the right parasymphyseal fracture; and closed treatment of the left condyle fracture. Four weeks later, the patient was converted to orthodontic appliances, and orthodontic treatment continued in preparation for jaw reconstruction. Six months after the maxillofacial injuries and with orthodontic preparation complete, he underwent definitive jaw and intranasal surgery to improve the airway, occlusion, and facial morphology. The patient's procedures included maxillary Le Fort I osteotomy (vertical lengthening and horizontal advancement); bilateral sagittal split osteotomies of the mandible (lengthening of the left posterior facial height and horizontal advancement); septoplasty; and the reduction of the inferior turbinates. Orthodontic maintenance and detailing continued until the appliances were removed 6 months after surgery. **C,** Oblique facial views before and after reconstruction. **D,** Profile views before and after reconstruction.

Chapter 28).[4,9,51,54,55,72,75,97,107] If the initial fracture occurred during childhood and was followed by condylar resorption, then additional secondary deformities of the maxilla and chin will have also occurred during growth. In addition to reconstruction of the ipsilateral mandible with a costochondral graft, surgical correction of the maxilla above and the chin below is often required. This includes use of Le Fort I osteotomy (primarily for cant and dental midline correction); contralateral sagittal split ramus osteotomy (asymmetry correction); and osseous genioplasty[7] (see Fig. 35-8).

When a displaced condylar fracture occurs in an adult and healing involves the loss of the ipsilateral posterior facial height, a predictable shift in the occlusion is also expected (Figs. 35-10 through 35-15). Depending on the individual's masticatory musculature and condylar (TMJ) adaptations, a significant centric relation–centric occlusion discrepancy may have occurred.[52,130,134] This can result in difficulty with chewing, swallowing, speech, secondary occlusal trauma, symptomatic TMD, and significant facial asymmetry. If so—and assuming satisfactory mandibular mobility (i.e., vertical mouth opening)—standard sagittal split ramus osteotomies can generally be carried out to reestablish the following: 1) the ipsilateral posterior facial height; 2) a consistent preinjury occlusion; 3) the restoration of facial

Text continued on p. 1521

• **Figure 35-11** A woman in her late 20s was in a bicycle accident and sustained a displaced right condylar fracture and anterior maxillary dentoalveolar trauma. She underwent open reduction and internal fixation of the right condyle fracture with plate and screw fixation. There was partial necrosis of the proximal (condylar) segment with a loss of posterior facial height. This resulted in a shift of the mandible on the ipsilateral side. There was a significant centric relation–centric occlusion discrepancy; the patient had difficulty chewing, symptomatic temporomandibular disorder, and facial asymmetry. She was referred to this surgeon and underwent perioperative orthodontics, bilateral sagittal split ramus osteotomies, and an osseous genioplasty. **A,** Frontal facial and occlusal views before reconstruction. **B,** Panorex radiograph before reconstruction.

• **Figure 35-12** A woman in her late 20s was a pedestrian who was struck by a motor vehicle. She sustained a right condylar fracture, a right parasymphyseal fracture, and maxillary dentoalveolar trauma. Primary fracture management included open reduction and internal fixation of the right condyle fracture, closed reduction of the right parasymphyseal fracture, and closed reduction of the dentoalveolar injury. She arrived to this surgeon for the evaluation of secondary deformities that included the partial resorption of the condylar segment, malunion of the parasymphyseal fracture (widening), and the loss of maxillary dentoalveolar components. Comprehensive evaluation included additional consultations with an orthodontist, a periodontist, and a restorative dentist. Surgery included bilateral sagittal split ramus osteotomies (correction of asymmetry), right parasymphyseal osteotomy (narrowing), and bloc iliac grafting of the maxillary dentoalveolar defects. Dental implants were placed 4 months later. Restorative work was completed 6 months after implant placement. **A,** Frontal view before secondary reconstruction. The Panorex radiograph indicates the loss of condylar height. The anteroposterior cephalometric radiograph and facial views indicate mandibular width asymmetry.

• **Figure 35-13** A woman in her 20s was in a moped accident and sustained maxillofacial trauma that included a displaced left condyle fracture, a right parasymphyseal fracture, maxillary dentoalveolar trauma, and the laceration of the upper lip. She was initially treated with closed reduction of the left condyle fracture, open reduction and internal fixation of the right parasymphyseal fracture, debridement of the right maxillary incisors, and reimplantation of the left maxillary incisors. By 3 months after treatment, malunion of the mandible resulted in malocclusion, difficulty chewing, symptomatic temporomandibular disorder, and facial asymmetry. The patient was referred to this surgeon for comprehensive evaluation included additional consultation with a periodontist, and an orthodontist. She underwent preoperative orthodontics and reconstruction that included bilateral sagittal split ramus osteotomies. A bloc corticocancellous graft was simultaneously crafted and secured to the anterior maxillary dentoalveolar defect. Four months later, four dental implants were placed. This was followed 4 months later by the placement of crowns. **A,** Frontal and occlusal views 1 week after the accident and primary fracture management. **B,** Panorex radiograph taken just after primary fracture management.

Centric relation (CR) bite

Centric occlusion (CO) bite

• **Figure 35-14** When he was between 13 and 15 years old, this patient underwent standard orthodontic treatment and achieved a normal occlusion without a centric relation–centric occlusion (CR-CO) discrepancy. When he was 16 years of age, he was in a motor vehicle accident and sustained injuries that included a displaced left condyle of the mandible fracture. The fracture was treated with closed treatment and intermaxillary fixation for 2 weeks followed by guiding elastics for an additional 4 weeks. The patient also sustained fracture of the left mandibular first and second molars, which required the placement of full crowns. With healing, there was a loss of posterior facial height and a shift of the mandible toward the fracture. There was a significant CR-CO slide with masticatory muscle discomfort and left temporomandibular joint noise. The patient underwent computed tomography scanning and magnetic resonance imaging of the temporomandibular joint, which indicated the following: left condylar head flattening and remodeling; the meniscus being in good alignment with a deformed condylar head; and, on the right side, the mandibular condyle and meniscus appear to be unremarkable. The patient maintained an adequate range of mandibular motion. He was being treated with a splint that prevented CR-CO slide, and his temporomandibular disorder has improved. Bilateral sagittal split osteotomies of the mandible were recommended to establish a consistent CR-CO without prematurities. **A,** Facial views 2 years after left condyle fracture with closed reduction. **B,** Intraoral views with the patient in CR bite. **C,** Intraoral views with the patient in CO bite.

Orthognathic Surgery; J.C. Posnick

• **Figure 35-15** A middle-aged man had a syncopal episode and sustained a displaced right condyle fracture of the mandible and maxillary dentoalveolar trauma. This was managed with closed treatment and 2 weeks of intermaxillary fixation followed by elastics, masticatory muscle retraining, and then dental rehabilitation. A comfortable occlusion with minimal centric relation–centric occlusion discrepancy and resolution of temporomandibular disorder was possible without the need for surgical intervention. **A,** Facial and occlusal views 2 days after injury. **B,** Panorex radiograph 4 weeks after injury that indicates right subcondylar fracture and dislocation and left maxillary dentoalveolar trauma.

• **Figure 35-15, cont'd C,** Frontal view at 18 months after injury. Effective muscle retraining achieved a stable occlusion. With wide vertical opening, there is a shift of the chin to the right. The centric occlusion view is shown 18 months after injury with successful dental rehabilitation.

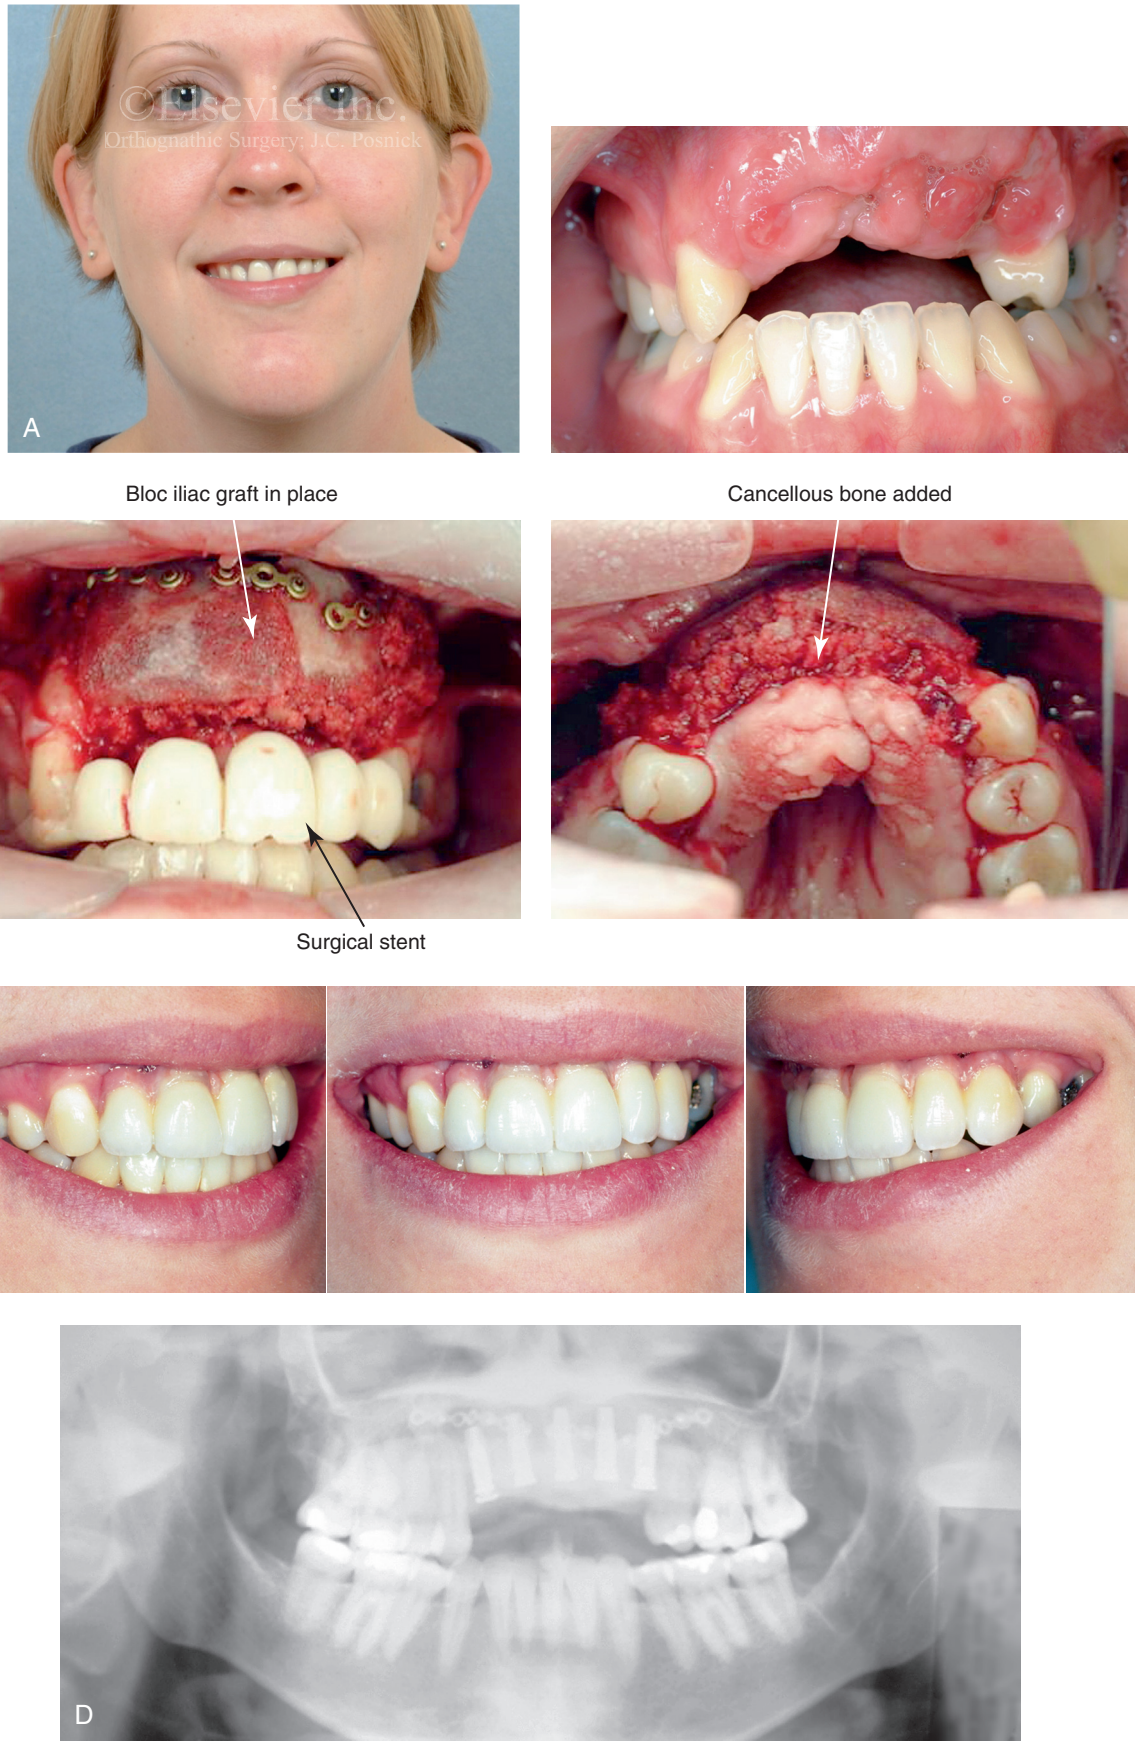
symmetry; and 4) the relief of TMD (see Chapter 4 and Figs. 35-10 through 35-15). In most cases, after the individual sustains a displaced condyle fracture, the combination of condylar remodeling and masticatory muscle adaptation will result in a manageable occlusion and an adequate range of motion without the need for secondary reconstruction (see Fig. 35-15).

Posttraumatic Segmental Dentoalveolar Defects

A frequently seen pattern of posttraumatic secondary deformity occurs after the avulsion or devascularization of an anterior dentoalveolar segment (i.e., the maxilla, the mandible, or both).[39] This may occur as an isolated injury or in conjunction with other jaw fractures (Figs. 35-16 and 35-17; see also Figs. 35-4, 35-9, 35-12, and 35-13). To secondarily correct this segmental dentoalveolar deformity with a loss of teeth, an autogenous corticocancellous iliac bone graft fixed in place with microplates and screws is generally a reliable option (see Figs. 35-4, 35-9, 35-12, 35-13, 35-16, and 35-17). This is followed by a soft-tissue vestibuloplasty and a keratinized mucosa grafting procedure, when required. Approximately 4 months after successful bone grafting and soft tissue re-arrangment, dental implants are placed. This is followed several months later with crown restorations. Comprehensive skeletal reconstruction and dental rehabilitation of segmental dentoalveolar defects generally involves a surgeon, a periodontist, and a restorative dentist and is best coordinated from the onset.[87]

Conclusions

Despite every attempt to ensure the optimal primary treatment of craniomaxillofacial fractures, a percentage of individuals present with residual facial deformities and head and neck dysfunction that require secondary reconstruction. Specific patterns of secondary maxillofacial deformities are frequently seen, including TMJ ankylosis, saddle-nose



• **Figure 35-16** A 28-year-old woman was in a motor vehicle accident and sustained maxillary dentoalveolar trauma with a loss of five anterior teeth and associated alveolar bone. She had previously undergone orthodontic treatment including 4 bicuspid extractions to close an anterior open bite. **A,** Frontal view with temporary partial denture in place. Occlusal view with the removal of the partial denture indicates the extent of dentoalveolar injury and bone loss. **B,** Intraoperative view with a crafted corticocancellous iliac graft fixed in place. A prefabricated stent was used to assist with graft positioning and contouring. **C,** Occlusal views after successful grafting, placement of 5 implants and then dental restorative work. **D,** Panorex radiograph after successful grafting and the placement of five dental implants.

• **Figure 35-17** A 21-year-old woman was in a motor vehicle accident and sustained naso–orbital–ethmoid fractures, left anterior maxillary dentoalveolar trauma with a loss of three teeth, and associated alveolar bone and left posterior mandibular dental injuries. She was initially treated at another institution. She was referred to this surgeon 6 months later, with left and right enophthalmus, saddle-nose deformity, and right and left medial canthal drift. She underwent left and right orbital reconstruction, left and right medial canthopexies, and the correction of the saddle-nose deformity with a full-thickness cranial graft (radix to tip) through a coronal scalp incision. She was treated by her local dentist with a removable maxillary partial denture. She returned to this surgeon for further maxillofacial evaluation 14 years later in the hopes of achieving improved dental rehabilitation. Examination confirmed left anterior maxillary dentoalveolar defect, left posterior mandibular absent second bicuspid and first molar, and several teeth with root canals. She agreed to a comprehensive dental rehabilitation approach. Additional evaluation by a periodontist, and a prosthodontist, was carried out. The patient also complained of chronic obstructed nasal breathing. Intranasal examination confirmed septal deviation and enlarged inferior turbinates. She underwent periodontal treatment followed by temporization of the dentition. Surgical procedures included septoplasty; inferior turbinate reduction; and reconstruction of the maxillary dentoalveolar defect with an autogenous corticocancellous iliac bloc graft. Four months later, three dental implants were placed in the anterior maxillary region. She also underwent implant placement in the left posterior mandible and the right posterior maxilla. Six months after implant placement, definitive crown placement and bridgework were initiated. **A,** Frontal views with smile before and after comprehensive secondary jaw and dental rehabilitation.

deformities, orthognathic deformities, and segmental dentoalveolar defects. Although there are few published reports that specifically address the management of posttraumatic secondary maxillofacial deformities, the application of basic orthognathic and dento-alveolar restorative principles will result in a favorable outcome for most patients. A team approach with coordinated efforts by the maxillofacial surgeon, the orthodontist, the restorative dentist, and the periodontist is often advantageous for the achievement of optimal results.

Idiopathic Condylar Resorption: Evaluation and Treatment

JEFFREY C. POSNICK, DMD, MD

- Theories of Etiology
- Clinical Perspectives
- Current Clinical Approach to Correction of the Secondary Jaw Deformities
- Brief Overview of Author's Current Thinking
- Case Presentations
- Conclusions

In patients with the condition of uncertain etiology that is commonly referred to as *idiopathic condylar resorption* (ICR)*, the condyles of the mandible partially resorb, thereby causing a loss of condylar height with secondary alterations of the maxillofacial morphology, occlusion, and head and neck function.[34,43,100] *Progressive condylar resorption* (PCR)* is a general term that is used to describe conditions that result in a similar loss of condylar height and secondary effects but with known associations (e.g., juvenile idiopathic arthritis, including any of its seven subtypes).[13,24,59,76,92,93]

In general, ICR has the following features:

- It generally affects girls and women who are between the ages of 15 and 35 years.
- It is most frequent among teenage girls during the pubertal growth spurt.
- It typically results in bilateral symmetric condylar involvement followed by stabilization (remission). In the majority of affected individuals, limited further resorption occurs. Unfortunately, in some, a second episode will result in the further loss of condylar height.
- There is no agreed-upon and proven etiology. ICR frequently seems to occur as part of the natural course of events rather than in conjunction with active therapy or treatment. It may also coincide with or be observed during or after active dental restorative, orthodontic, or surgical interventions.
- During the active phase of condylar resorption, TMJ and masticatory muscle discomfort is expected. The active phase often subsides within 6 to 12 months.
- When the condition becomes quiescent, the individual is generally left with satisfactory TMJ function without significant limitations in mouth opening or intracapsular pain. Persistent joint noise is frequent.
- Head and neck functions are likely to be negatively impacted including: chewing; breathing; speech articulation; and body image.
- When the condition is in remission, a cartilaginous cap over an intact cortical rim can generally be documented. A deflated or diminished condylar head is generally seen on imaging (e.g., magnetic resonance imaging or computed tomography scanning). The glenoid fossa and the articular disc typically remain biologically intact.

Mandibular and occlusal findings generally include the following:

- Change in the shape of the condylar heads (i.e., flattening and thinning)
- Decrease in condylar height
- Loss of overall posterior facial height
- Mandibular retropositioning with clockwise rotation (high angle)
- Angle Class II anterior open bite, excess overjet malocclusion

Theories of Etiology

The current dominant theory holds that the etiology of ICR is hormonally mitigated, immunologically controlled and may arise in genetically susceptible individuals in conjunction with environmental factors.* Sex hormones are thought to modulate biochemical changes within the TMJ, which

*These terms are likely to change as further knowledge becomes available.

*References 1, 3-7, 15, 23, 28, 29, 31, 42, 51, 58, 65, 79, 86, 99, 111, 113

may then result in condylar resorption. For some time, it has been suggested that there is alteration in the serum hormonal levels in at least some affected girls and women with ICR.[31] Gunson and colleagues described endocrine function among women who arrived at their clinic with a history, physical examination, and radiographic findings that were consistent with ICR. The average age at presentation was 26 years (range, 15 to 45 years).[31] Twenty-five of the 27 patients (93%) had low levels of serum 17-beta estradiol at the mid-menstrual cycle. Two subgroups were further differentiated. The first group did not produce estrogen naturally (8 out of 27 patients), and the second group (19 out of 27 patients) had low 17-beta estradiol levels that were presumed to be the result of oral contraceptive pill usage. The authors theorize that, whether the condition is induced by ethinyl estradiol (i.e., oral contraceptive pills) or by premature ovarian failure, a low circulating 17-beta estradiol serum level negatively affects the natural reparative capacity of the condyles. The authors believe that, when 17-beta estradiol deficiency is coupled with the presence of local factors that cause compressive forces, condylar lysis is more likely to occur and to ultimately result in the observed condition called ICR.[8,14,27,46,64] Unfortunately, the study did not include a control group for oral contraceptive pill use or precise knowledge of the phase of the menstrual cycle at the time of hormone serum sampling. Although hormone influences no doubt play a role, an autoimmune aspect is also likely.[31]

Gunson and Arnett comment that whatever the underlying etiology of ICR, all bone loss at the condylar level involves a *common resorptive pathway* that includes cytokine-activated osteoblasts that then recruit and promote the activity of osteoclasts.[32] This in turn results in the secretion of enzymes that are responsible for the breakdown of hydroxyapatite and collagen. A case in point is *juvenile idiopathic arthritis* (ex. polyarticular arthritis, rheumatoid factor positive), which is caused by a B-cell–mediated autoimmune reaction to synovial tissues.[33,80,105] A consequence of this reaction is the presence of local inflammatory cells, which secrete cytokines that cause the activation of osteoblast-mediated osteoclast catabolism.[89] The end result is bone breakdown through the common resorptive pathway.[30] In patients with juvenile idiopathic arthritis (JIA), a current treatment approach is to minimize articular bone loss by using pharmacologic drugs that interfere with specific cytokines and enzymes along the common resorptive pathway rather than open joint or joint replacement procedures. This may include non-steroidal anti-inflammatories (NSAIDS) or other drugs such as methotrexate or a newer class of medications called biologicals.[10,35,36,39,48,52,80,105] Gunson and Arnett point out that a similar approach to ICR may prove to be useful.[32]

Another theory of the cause of ICR is avascular necrosis of the condyle as a result of the compression of specific vessels that supply the condyle followed by condylysis, loss of condyle height with secondary jaw deformity and malocclusion.[16,17,45,62,72,81-84] Piper and Choung had speculated that pathologic compressive forces of the posterior aspect of the condyle on the ligamentous retrodiscal soft tissues constrict the small vessels, thereby limiting circulation to the condyles with resulting in aseptic necrosis that accounts for the observed condylysis in patients with ICR.[17,72] They went on to hypothesize that either a chronically dislocated non-reducing disc or specific patterns of malocclusion may also cause this cycle of events. As an extension of this thinking, preventative open-joint procedures were offered to alleviate the theoretical compression of the condylar circulation. Those of us that are skeptical of the non-reducing disc cause of ICR point out that the almost universally observed bilateral symmetric simultaneous nature of this condition and its occurrence only in females make the theory an improbable explanation.

Clinical Perspectives

The foregoing theories remain unproven, but the effects of estrogen on condylar resorption and repair with or without an autoimmune component seem indisputable. Further studies will be required to determine the additive effects of occlusion and masticatory muscle forces on the TMJ in the presence of hormonal imbalance, autoimmune influences, genetic predisposition and other environmental factors.

Some clinicians suggest that, with a lack of clarity about either the etiology of the condition or the effects of various treatment modalities and without a guaranteed endpoint to the condylar degeneration in any given patient, it is best to remove the affected condyles and either reconstruct them with a *costochondral (rib) graft* or to remove the whole joint (i.e., the condyle, the disc, and the glenoid fossa) and replace it with an *alloplastic total joint*. Proponents of a partial or total joint replacement approach to the management of ICR are correct in their thinking that the only way to be certain that a further loss of posterior facial height will not continue is to remove and replace the condyle.[55,56,107,110] For the great majority of patients with ICR, joint replacement treatment seems radical on the basis of the following: 1) the unlikely probability of long-term TMJ pain 2) the expected satisfactory long-term mandibular (mouth) opening 3) the expected condylar stabilization ("burn-out") that is typically seen and 4) the known potential for perioperative complications with invasive open joint procedures and the long-term failure rates of total joint replacement.

Mercuri presents an alternative point of view with a recommendation for total joint replacement to "eliminate the variable issue of ongoing condylar resorption."[55,56] He offers total alloplastic reconstruction as a definitive solution. He also states that the non-alloplastic (biologic) condyle option (e.g., costochondral grafting) requires stabilization of the graft with minimal mobility while integration (union) to the host mandibular occurs. This limits early masticatory muscle rehabilitation, which he feels is contrary to the tenets of physical rehabilitation after joint surgery. The

disadvantages of alloplastic total TMJ reconstruction include the following: 1) the cost of the device 2) the expected material wear 3) the potential for long-term instability and failure 4) the incidence of both early and late complications including infections with the associated need for device removal and 5) the fact that alloplastic implants will not follow a patient's normal growth pattern. Joint replacement advocates admit that patients must be advised that alloplastic total TMJ reconstruction devices are expected to have a limited functional life. In addition, the total joint replacement approach requires the removal of the functional glenoid fossa and disc along with excision of the condylar head, neck, and posterior ramus on both sides.

Recommendations regarding how best to limit progression of condylar resorption and then how to treat the consequences of ICR depend on the clinician's beliefs about the following 1) the disorder's likely etiology 2) the effects of malocclusion and the masticatory muscle forces and 3) the natural history of the degenerative process.

Some clinicians speculate that, if "decompressive" TMJ treatment is initiated early during the clinical course of active ICR, then less condylar resorption will occur. Others believe that, after the resorptive process has begun, it runs its course despite any attempt to "unload" the joint. Even with a lack of evidence-based research into the subject, most clinicians recommend attempts to limit mechanical compressive TMJ forces through the use of conservative measures (i.e., splints, muscle relaxants, medications and, diet modifications) in the hopes that less resorption (condylysis) will occur.[11,12,19,21,25,37,40,47,63,66,101] Some authors believe that counterclockwise rotation of the maxillomandibular complex as part of the orthognathic correction will increase the compressive condylar forces, whereas others state that it is actually a method of "unloading" the joint.[20,22,41,44,50,57,61,71,85,88,105,108] I agree with the published studies that document long-term skeletal stability when counterclockwise rotation of the maxillomandibular complex is carried out as part of the correction of mandibular-deficient dentofacial deformity.[74,75,77,109] A common concern is that TMJ "loading" (i.e., the presence of compressive forces) will occur if the condyles are "overseating" or if medial or lateral condylar torquing is allowed to occur during orthognathic surgery.[3-6] Some clinicians speculate that individuals who have persistent TMJ symptoms (e.g., popping, clicking) after the orthodontic treatment and corrective orthognathic surgery are at higher risk for progression.[2] Most published studies confirm that joint noise (e.g., popping, clicking, grating) is not in itself an indicator of future condylar resorption.[60,87,104]

Current Clinical Approach to Correction of the Secondary Jaw Deformities

After the diagnosis of ICR is made, non-invasive measures (e.g., splint therapy, muscle relaxants, medications, and diet modification) to "unload" and "stabilize" the condyles or at least to relieve masticatory muscle hyperactivity and discomfort are initiated. Orthognathic procedures and orthodontic treatment carried out to correct the secondary malocclusion, the facial dysmorphology, and to open the airway are more likely to be maintained if the condylar resorption process has been stable for a period of time.[49,77,112] Stability can be documented by minimal ongoing change in the occlusion, an intact cartilaginous cap, and an underlying rim of cortical bone over the partially resorbed condyle. The judicious use of technetium-99m methylene diphosphonate quantitative condylar bone scintigraphy can be a helpful tool for assessing whether or not condylysis is active.[9,18,26,53,69,70,73,78,90,103] Unfortunately, these and other tests only confirm the current anatomy and activity level; they cannot predict the future.

The resulting maxillomandibular dysmorphology observed in patients with ICR can affect speech, swallowing, chewing, breathing, and lip closure. ICR rarely results in disabling facial or TMJ pain or significant limitations in vertical mouth opening. The observed facial aesthetic consequences of ICR are the result of the maxillo-mandibular changes which distort but do not actually deform the soft-tissue envelope. The overlying soft tissues of the lips, cheeks, and neck and the underlying soft tissues of the tongue and soft palate can be normalized only by correcting the skeletal deformities. The achievement of favorable facial aesthetics and the opening of the airway generally require the surgical repositioning of the maxilla (Le Fort I osteotomy), the mandible (ramus osteotomies), and the chin region (oblique osteotomy). Limiting the surgery to either the maxilla or the mandible with the idea of achieving a more stable occlusal result is not substantiated in the literature and is likely to result in suboptimal results. The key to achieving a successful outcome (i.e., enhanced aesthetics, improved occlusion, and an open airway) for the majority of patients with ICR is to surgically accomplish adequate horizontal advancement of the entire maxillomandibular complex often with counterclockwise rotation.

The suggestion that, for the patient who has experienced ICR, the use of distraction osteogenesis techniques rather than standard orthognathic procedures will achieve a more stable long-term occlusion is not supported by the literature.[38,54,68,91,94,95,102] The distraction approach 1) generally limits the region of reconstruction to the mandible 2) it requires greater patient convalescences and compliance, and 3) it may increase (rather than decrease) the compressive forces on the condyles.

When the condylar resorption process is believed to be "burnt out," a comprehensive approach to correct the secondary deformities that involves an orthodontist, an orthognathic surgeon, a TMJ specialist, and appropriate imaging studies is recommended. Periodontal and restorative dental work may also be needed. Evaluation by a rheumatologist should also be considered. A thorough

evaluation of the upper airway is essential to clarify any day and nighttime breathing difficulties. The simultaneous correction of chronic nasal airway obstruction and any baseline obstructive sleep apnea should be a primary objective (see Chapters 10 and 26).

The key to a favorable reconstruction for an individual with end-stage ICR or PCR is to define the functional disability (i.e., breathing, chewing, speech, swallowing, lip closure) and the extent of skeletal dysmorphology. The establishment of a functional occlusion that limits stress in the entire masticatory system without significant centric relation–centric occlusion discrepancies and without parafunctional habits is desirable (see Chapter 9). The successful performance of orthognathic, intranasal, and dental procedures to achieve these objectives represents our standard approach; see the case presentations later in this chapter.

Kaban and colleagues offers an alternative approach when the patient is not willing to take the risk that a degree of resorption may continue or reoccur at some point in the future.[24,43,67,92,96-98] The authors completed a retrospective case series of 15 patients with the diagnosis of active bilateral ICR who chose a condylar replacement approach between 1999 and 2004. Each patient underwent bilateral endoscopic-assisted condylectomy and autogenous costochondral graft reconstruction. Patients with the following characteristics were included:

1. Active bilateral ICR documented by worsening Class II malocclusion with open bite on serial clinical examinations, radiographs, photographs, and dental casts
2. A positive technetium-99m methylene diphosphonate bone scan
3. A minimum of 12 months of postoperative follow up

Symptoms such as myofascial pain and occlusal discomfort are managed by splint therapy, physical therapy, muscle relaxants, nonsteroidal anti-inflammatory drugs, and other modalities as indicated. Patients who respond to treatment as documented by the relief of symptoms, no occlusal radiograph changes over a 2-year period, and a negative bone scan begin orthodontic treatment in preparation for standard orthognathic surgery. Patients with active ICR who do not respond to the previously described treatment modalities or who prefer not to follow the protocol for a variety of reasons are considered candidates for condylectomy and costochondral graft reconstruction. Fifteen patients fell into this latter category and underwent bilateral endoscopic condylectomies and costochondral graft reconstruction. None of the 15 study patients suffered significant surgical complications, such as fractures or the erroneous placement of the graft within the fossa. Postoperatively, all patients showed Class I occlusion with no anterior open bite. All patients maintained a clinically acceptable and reproducible occlusion one year later with a mean maximum incisor mouth opening of 39 mm. Kaban and colleagues stressed the importance of making a distinction between active and inactive ICR and the patient's refusal to wait for the presumed remission of the active condylar resorption phase. Only those who were unwilling to risk recurrence are offered the condylar replacement option; all others undergo a standard orthognathic approach.

Brief Overview of Author's Current Thinking

With the osteoarthritic condition known as ICR or PCR, after the acute process "runs its course" (i.e., after 6 to 12 months for most individual's), a degree of bilateral condylar resorption will have occurred. This is typically followed by relative condylar stability, satisfactory range of motion of the mandible, and no significant TMJ limitations. The resulting anterior open bite Class II malocclusion may be responsible for masticatory muscle discomfort during function. Temporary relief of these symptoms with a neutralizing splint is generally possible.

The definitive correction of the secondary maxillomandibular deformity through standard osteotomies in combination with appropriate orthodontics has proven beneficial to improve the occlusion, to open the airway, and to enhance facial aesthetics. Concern about further resorption of the "fragile" condyles is best managed by avoiding masticatory activities that "load" (i.e., compress) the joint and with the use of systemic medications when indicated.[32]

The treatment of juvenile idiopathic arthritis (JIA) has improved dramatically during recent years with the advent of disease-modifying anti-rheumatoid drugs. The orthognathic surgeon will encounter patients on a drug regimen that consists of nonsteroidal anti-inflammatory drugs [NSAIDS], glucocorticoids, methotrexate, and biologic agents. In these cases, consultation with a rheumatologist is recommended, but the surgeon should also be aware of these medications, because their presence could affect surgical outcome. Prudent perioperative management of these drugs is necessary to optimize surgical outcome. A balance must be struck between minimizing potential surgical complications and maintaining disease control to prevent further joint damage (i.e., condylar resorption) that would negatively affect the outcome.[41A]

To review, ICR should not be managed either as a standard internal derangement or as a typical temporomandibular disorder (TMD). The concept of resolving the problem through either an open-joint procedure or through joint replacement continues to seem off the mark given the known natural history of this entity for the majority of affected individuals. A joint-replacement approach is generally reserved for those few patient who have undergone failed surgical procedures with additive iatrogenic TMJ dysfunction.

Case Presentations

CASE 36-1

Progressive Condylar Resorption (Fig. 36-1)

History

A 23-year-old Caucasian female was diagnosed with juvenile rheumatoid arthritis when she was 10 years old; the disease primarily affects her knees and ankles. Involvement of both of her TMJs began when she was 12 years old and resulted in PCR that stabilized when she was 14 years old. She underwent compensatory orthodontics when she was between the ages of 14 and 16 years, and she has reported pain-free satisfactory mandibular range of motion since that time. When she was 19 years old, she sustained trauma to

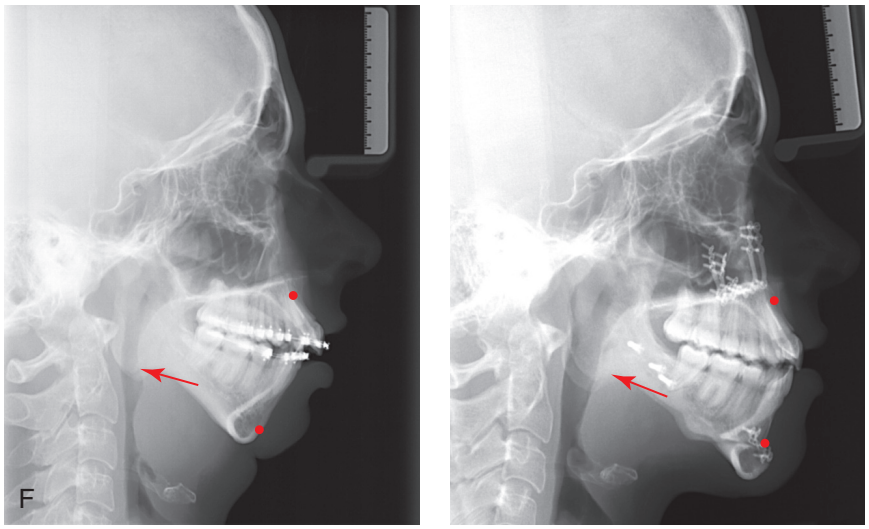
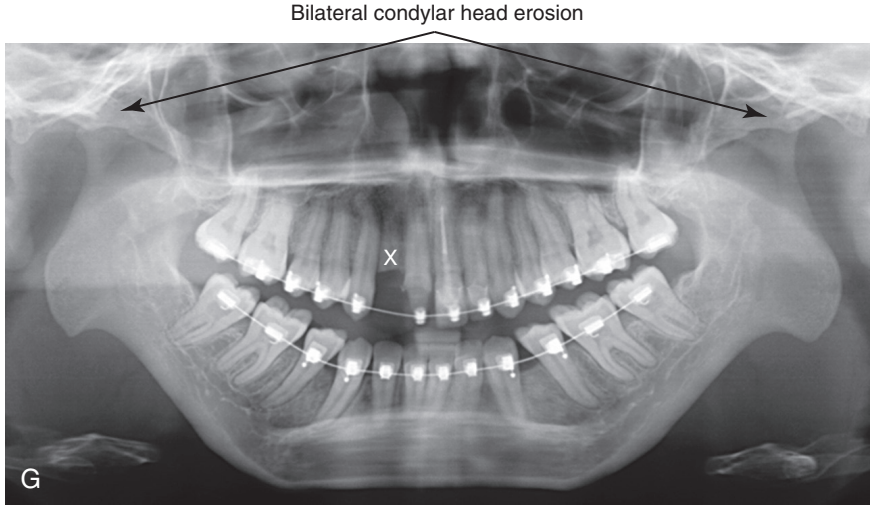
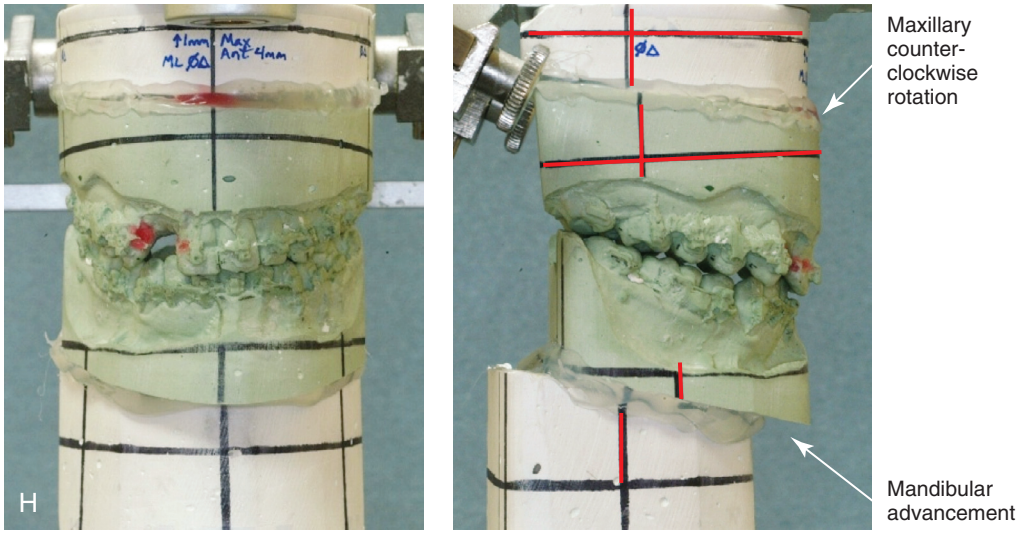
After treatment

• **Figure 36-1, cont'd E,** Occlusal views before retreatment, before surgery but after bicuspid extractions, and after surgery.







• **Figure 36-1, cont'd F,** Lateral cephalometric views before and after surgery. **G,** Panorex view before surgery. An "X" is on a root tip that requires extraction. A question mark is on an incisor that may require extraction. **H,** Articulated dental casts that indicate analytic model planning. *From Posnick JC, Fantuzzo JJ: Idiopathic condylar resorption: current clinical perspectives,* J Oral Maxillofac Surg *65:1617-1623, 2007.*

the four maxillary incisors with a loss of the right lateral incisor and the need for root canal treatment of the right central incisor. Temporary restorations were placed. The patient then continued to follow up with a general dentist and orthodontist when she was between 19 and 23 years old, with no changes noted in her occlusion (i.e., no progress of the condylar resorption).

Evaluation

The 23 year old woman arrived for surgical consultation in the hope of achieving enhanced facial aesthetics and improved function (i.e., mastication, breathing, lip posture, and speech articulation). She underwent evaluations by a speech pathologist, an otolaryngologist/head and neck surgeon, an orthodontist, a periodontist, a restorative dentist, a rheumatologist, and a TMJ specialist.

Treatment

Preoperative orthodontic treatment included the removal of the mandibular first bicuspids to uncrowd the arch. Unfortunately, as a result of previous dentoalveolar trauma, only minimal repositioning of the maxillary anterior teeth was possible, thereby preventing optimal incisor positioning. The patient's surgery included the following:

- Maxillary Le Fort I osteotomy
  - Vertical intrusion at the incisors
  - Maxillary plane counterclockwise rotation
  - Horizontal advancement at the incisors
- Bilateral sagittal split ramus osteotomies
  - Mandibular plane counterclockwise rotation
  - Horizontal advancement
- Oblique osteotomy of the chin
  - Horizontal advancement
  - Vertical shortening
- Intranasal procedures
  - Septoplasty
  - Reduction of the inferior turbinates

After the initial surgical healing (5 weeks), finishing orthodontics continued for 6 months. The removal of the orthodontic appliances was followed by maintenance splint therapy and orthodontic retention that was primarily used while the patient was sleeping.

CASE 36-2

Idiopathic Condylar Resorption (Fig. 36-2)

History

This systemically healthy 12-year-old girl experienced severe TMJ discomfort with limited and painful mouth opening. Mandibular retrusion and anterior open-bite deformity were progressive over the subsequent 6 months. When the patient was 13 years old, her orthodontist offered maxillary first bicuspid extractions with orthodontic retraction to neutralize the occlusion. From the ages of 13 to 15 years, orthodontic treatment accomplished this objective. When the patient reached the age of 16 years, concerns about her facial aesthetics, her airway, and her periodontal health were voiced, and alternative treatment was sought.

Evaluation

A 16 year old teenager arrived for surgical evaluation without pain in the TMJ and facial region. Vertical mouth opening was to 35 mm. Radiographs confirmed no progression of condylar resorption for at least 2 years. A complete workup for systemic joint disease was negative. The patient described having difficulty breathing through her nose, and she was found to have a deviated septum and hypertrophic inferior turbinates.

Treatment

Redo orthodontic treatment included the removal of the mandibular first bicuspid teeth to uncrowd the arch and upright the incisors. The patient's surgery included the following:

- Maxillary Le Fort I osteotomy
  - Vertical intrusion at the incisors
  - Maxillary plane counter clockwise rotation
  - Horizontal advancement at the incisors
  - Cant correction
- Bilateral sagittal split ramus osteotomies
  - Mandibular plane counterclockwise rotation
  - Horizontal advancement
- Oblique osteotomy of the chin
  - Horizontal advancement
  - Vertical shortening
- Intranasal procedures
  - Septoplasty
  - Reduction of the inferior turbinates
- Removal of wisdom teeth

After initial surgical healing (5 weeks), finishing orthodontics continued for 6 months. Removal of orthodontic appliances was followed by the use of routine removable retainers.

CASE 36-3

Idiopathic Condylar Resorption (Fig. 36-3)

History

A 12-year-old female underwent orthodontic treatment when she was between the ages of 12 and 15 years; including four bicuspid extractions. She was felt to have achieved a satisfactory occlusion without the need for further care. When she was 19 years old and away at college, she experienced an episode of temporomandibular disorder that involved TMJ region and masticatory muscle discomfort and that limited her mandibular range of motion and her ability to chew. Over a 6-month period, the symptoms subsided. During this time, a progressive anterior open-bite and a retrusive mandibular profile occurred. For the next two years (i.e., from the ages of 19.5 years to 21.5 years), she was followed by a restorative dentist and an orthodontist; no clinical progression was found. There were no further changes in her occlusion, but she did have intermittent masticatory muscle discomfort that improved with the use of an occlusion neutralization splint.

• **Figure 36-3** Patient before and after treatment. **A,** Frontal views in repose before and after treatment. **B,** Frontal views with smile before and after treatment.

Continued

Evaluation

The patient arrived for surgical consultation when she was 21 years old having just graduated from college with the hope of achieving improved function (i.e., mastication, breathing, lip posture/closure, and speech articulation) and enhanced facial aesthetics (i.e., an improved profile and a less gummy smile). She underwent evaluations by a speech pathologist, an otolaryngologist/head and neck surgeon, an orthodontist, a restorative dentist, and a TMJ specialist.

Treatment

With successful splint therapy for the relief of masticatory muscle discomfort and a 2-year history of no progression of condylar resorption (i.e., stable occlusion), orthodontic dental decompensation was initiated. A computed tomography scan of the TMJ was obtained before surgery. The patient's surgery included the following:

- Maxillary Le Fort I osteotomy
  - Vertical intrusion at the incisors
  - Horizontal advancement at the incisors
- Bilateral sagittal split ramus osteotomies
  - Mandibular plane counterclockwise rotation
  - Horizontal advancement
- Oblique osteotomy of the chin
  - Horizontal advancement
  - Vertical shortening
- Intranasal procedures
  - Septoplasty
  - Reduction of the inferior turbinates
  - Recontouring of the nasal floor
- Removal of retained wisdom teeth

After initial surgical healing (5 weeks), finishing orthodontics continued, with the removal of the appliances 6 months postoperatively. The patient continued with preventative splint therapy and orthodontic retention.

CASE 36-4

Progressive Condylar Resorption/Idiopathic Condylar Resorption? (Fig. 36-4)

History

When she was 15 years old, the occlusion of this female high school student was characterized as having a normal overjet/overbite relationship, with mild anterior crowding. When she was 16 years of age, she experienced an episode of temporomandibular disorder that was characterized by TMJ region and masticatory muscle discomfort. This was accompanied by a painful and limited mandibular range of motion and chewing difficulties. When she was 17 years old, the TMD was successfully managed with the use of conservative measures (e.g., splint therapy, anti-inflammatory agents, and diet modifications). Mouth opening was satisfactory and without direct TMJ region pain but with an anterior open-bite skeletal Class II malocclusion. As a result of other signs and symptoms that were present, a diagnosis of chronic fatigue syndrome and fibromyalgia was made.

Evaluation

The patient arrived for surgical consultation when she was 19 years old in the hopes of achieving improved function (i.e., mastication, breathing, lip closure/posture, speech articulation, and swallowing) and enhanced facial aesthetics (i.e., smile and profile). She underwent evaluation by a speech pathologist, an otolaryngologist/head and neck surgeon, an orthodontist, a TMJ specialist, a restorative dentist, and a general physician.

Treatment

With conservative measures used to control masticatory muscle discomfort, satisfactory TMJ function, and no clinical progression of condylar resorption after 2 years of observation, orthodontic dental decompensation was initiated. No extractions were required to relieve crowding. A computed tomography scan of the TMJ was obtained 2 months before surgery. The patient's surgery included the following

- Maxillary Le Fort I osteotomy
  - Vertical intrusion
  - Horizontal advancement
  - Segmentation for arch expansion and correction of the curve of Spee
- Bilateral sagittal split ramus osteotomies
  - Mandibular plane counterclockwise rotation
  - Horizontal advancement
- Oblique osteotomy of the chin
  - Horizontal advancement
  - Vertical shortening
- Intranasal procedures
  - Septoplasty
  - Inferior turbinate reduction
  - Nasal base recontouring
- Removal of Wisdom Teeth

After surgical healing (5 weeks), finishing orthodontics continued for 9 months. With the removal of the orthodontic appliances, preventative splint therapy and orthodontic retention continued.

CASE 36-5

Idiopathic Condylar Resorption (Fig. 36-5)

History

When she was 12 years old, she was referred by a pediatric dentist to an orthodontist for evaluation of her malocclusion. She was felt to have dental crowding, and she underwent standard orthodontic therapy (without extractions) when she was between 12 and 14 years old, after which time the appliances were removed. She was left with a mild gummy smile, satisfactory lip competence, and a stable Class I occlusion.

When she was approximately 22 years old, she experienced an episode of bilateral TMJ and masticatory muscle discomfort that affected her mandibular range of motion and her chewing ability. An insidious anterior open-bite and retrusive mandibular profile was recognized during the ensuing 6 to 12 months. The symptoms subsided, and the patient was left with a satisfactory mandibular range of motion without TMJ region discomfort. She returned to the treating orthodontist when she was 26 years old complaining of difficulty with chewing as a result of malocclusion and masticatory muscle discomfort. Radiographic examination confirmed the partial resorption of the condylar heads.

Evaluation

The patient initially arrived for surgical evaluation when she was 26 years old and requested reconstruction. The history, physical examination, and radiographic findings were consistent with ICR. Conservative management of the masticatory muscle discomfort and the confirmation of condylar stability were recommended. The patient continued with splint therapy. Over the next 12 months, a consistent occlusion with good mandibular range of motion confirmed condylar stability. As a result of her work and school schedules, the patient elected to postpone reconstruction until a future date.

She returned when she was 30 years old and again requested reconstruction. Now, with documentation of at least 5 years of no measurable progression of condylar resorption and with a negative quantitative condylar head bone scan, definitive therapy was offered. She underwent current evaluations by a speech pathologist, an otolaryngologist/head and neck surgeon, an orthodontist, a restorative dentist, and a general physician.

Treatment

Orthodontic dental decompensation was carried out over the course of 9 months. The patient's surgery included the following:

- Maxillary Le Fort I osteotomy
  - Vertical intrusion at the incisors
  - Horizontal advancement at the incisors
  - Maxillary plane counterclockwise rotation
- Bilateral sagittal split ramus osteotomies
  - Mandibular plane counterclockwise rotation
  - Horizontal advancement
- Oblique osteotomy of the chin
  - Horizontal advancement
  - Vertical change

After initial surgical healing (5 weeks), finishing orthodontics continued for approximately 6 months, and orthodontic retention continued. With good relief of masticatory muscle discomfort, the patient had a limited need for splint therapy.

Conclusions

In patients with the condition of uncertain etiology known as ICR and in those with a known association (PCR), the condyles of the mandible partially resorb, thereby causing a loss of condylar height and secondary alterations of the maxillo-mandibular complex with effects on the occlusion, the upper airway, and the facial aesthetics. Theories of the condition's etiology continue to evolve.

When the condylysis process is believed to be "burnt out," a comprehensive approach to resolve the secondary deformities generally involves an orthodontist, an orthognathic surgeon, a TMJ specialist, and appropriate imaging studies to achieve optimal results. The keys to a favorable result for the secondary maxillo-mandibular deformities are as follows: to await the presumed remission of condylar resorption; to define the functional deficits; and to then successfully perform joint-preserving orthognathic and intranasal procedures in conjunction with orthodontic treatment as indicated. In the future, the use of disease-modifying anti-rheumatic drugs may play a prominent role in limiting condylar resorption in affected individuals.

Hugo Obwegeser introduced the intraoral approach to completing an osseous genioplasty in 1957.[74] More than half a century later, this relatively simple technique still remains underused when surgeons are asked to make cosmetic changes to the chins of their patients.

Anatomy of the Chin

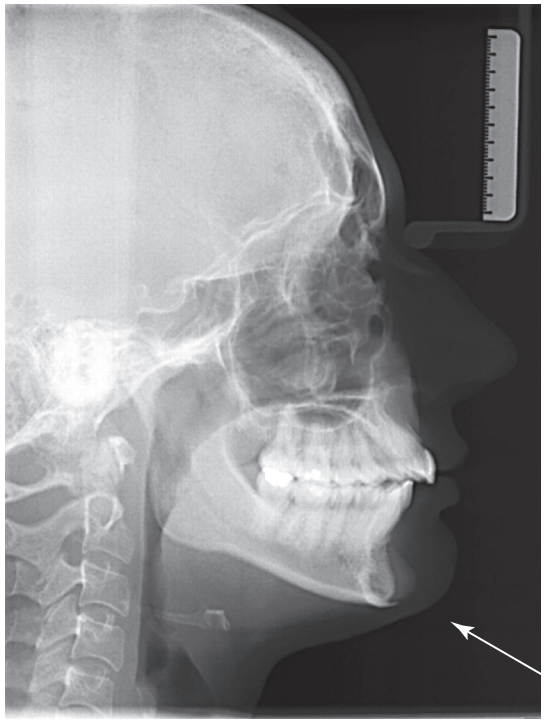
The word *chin* describes a region of the face that includes both soft tissue and bone.[79,125] The soft-tissue portion encompasses the labial mental fold superiorly, the oral commissures laterally (just anterior to the jowls), and the submental–cervical crease inferiorly. The bony portion of the chin encompasses the mandibular symphyseal region. It includes the region inferior to the root apices of the anterior teeth and the area in front of and below the mental foramen on each side. Within the soft tissues of the chin are found a series of paired muscles that include the mentalis, the quadratis labii inferioris, the triangularis, and the superior portions of the platysma that extend over the symphysis region.[22] Attached to the genial tubercle of the chin posteriorly are the tendinous attachments of the geniohyoid and genioglossus muscles.[66] The anterior bellies of the digastric muscles are attached to the posterior portion of the inferior border of the symphysis. The sensory innervation to the cutaneous chin, the lower lip, and the inner vestibule is derived from the mental nerve on each side. The motor innervation to the muscles within the soft tissues of the chin occurs through the marginal mandibular and cervical branches of the facial nerve.

Aesthetics of the Chin

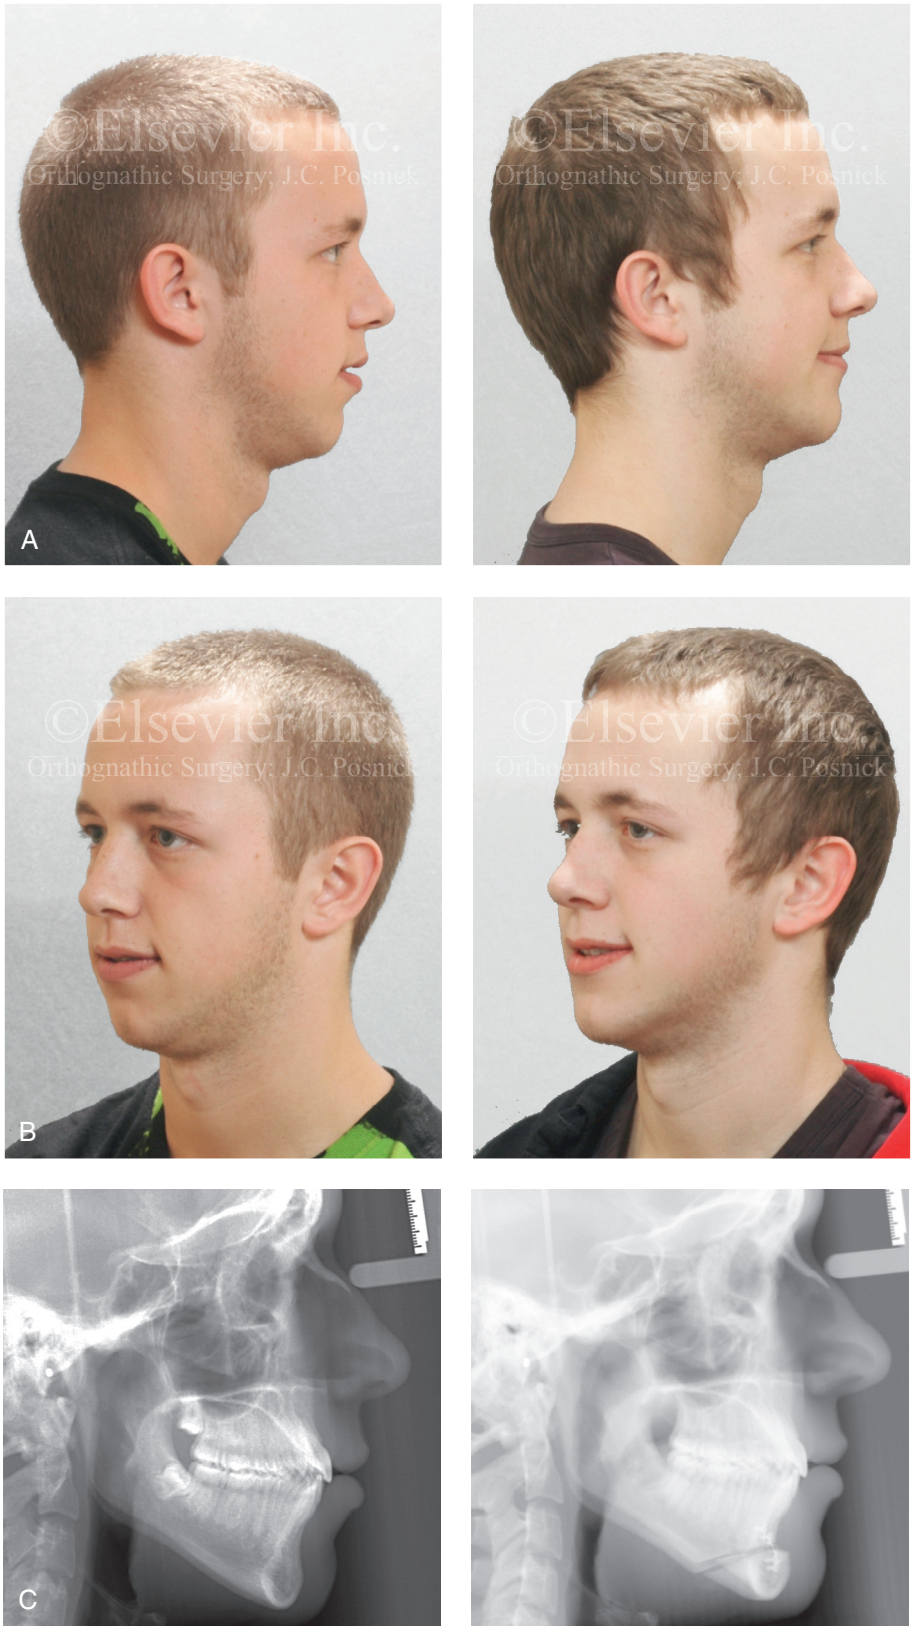
In Western society, a "weak" or deficient chin is associated with timidity, indecision, femininity, a lack of athleticism, and shy behavior. Conversely, a "strong" or forwardly projecting chin is associated with athleticism, aggressiveness, decisiveness, and bold behavior. The fact that an average adult from any number of ethnic backgrounds and nationalities from around the world will frequently characterize a chin as either "weak" or "strong" demonstrates the subliminal messages communicated about the character of a person as a result of the presenting chin morphology. When people speak about chin contour, emphasis is generally placed on the profile view (Fig. 37-1).[2,13,90,91] Although it is true that a retrusive pogonion is a frequently mentioned concern, the chin may also be asymmetric or out of the normal range in more than one dimension.

When it is taken with the patient in the natural head position, with the lips relaxed (i.e., in repose) and with the lower jaw at rest (i.e., the condyles seated in the fossa and with a normal freeway space between the teeth), a lateral cephalometric radiograph provides an accurate image of the facial skeleton and the overlying soft tissues from which to judge profile aesthetics.[28,30,31,43,44,83,105,112] When viewing either a full-face lateral photograph or a soft-tissue lateral cephalometric radiograph taken in this way, a vertical line (i.e., perpendicular to the floor with the patient in the natural head position) can be drawn through the subnasal region to assess the relative prominence of the nose, lips, and chin.[36] Ideally, the chin should lie on this line, with the lips slightly anterior (Figs. 37-2 through 37-5).[9] It is also true that there are many complex interrelationships

Text continued on p. 1571



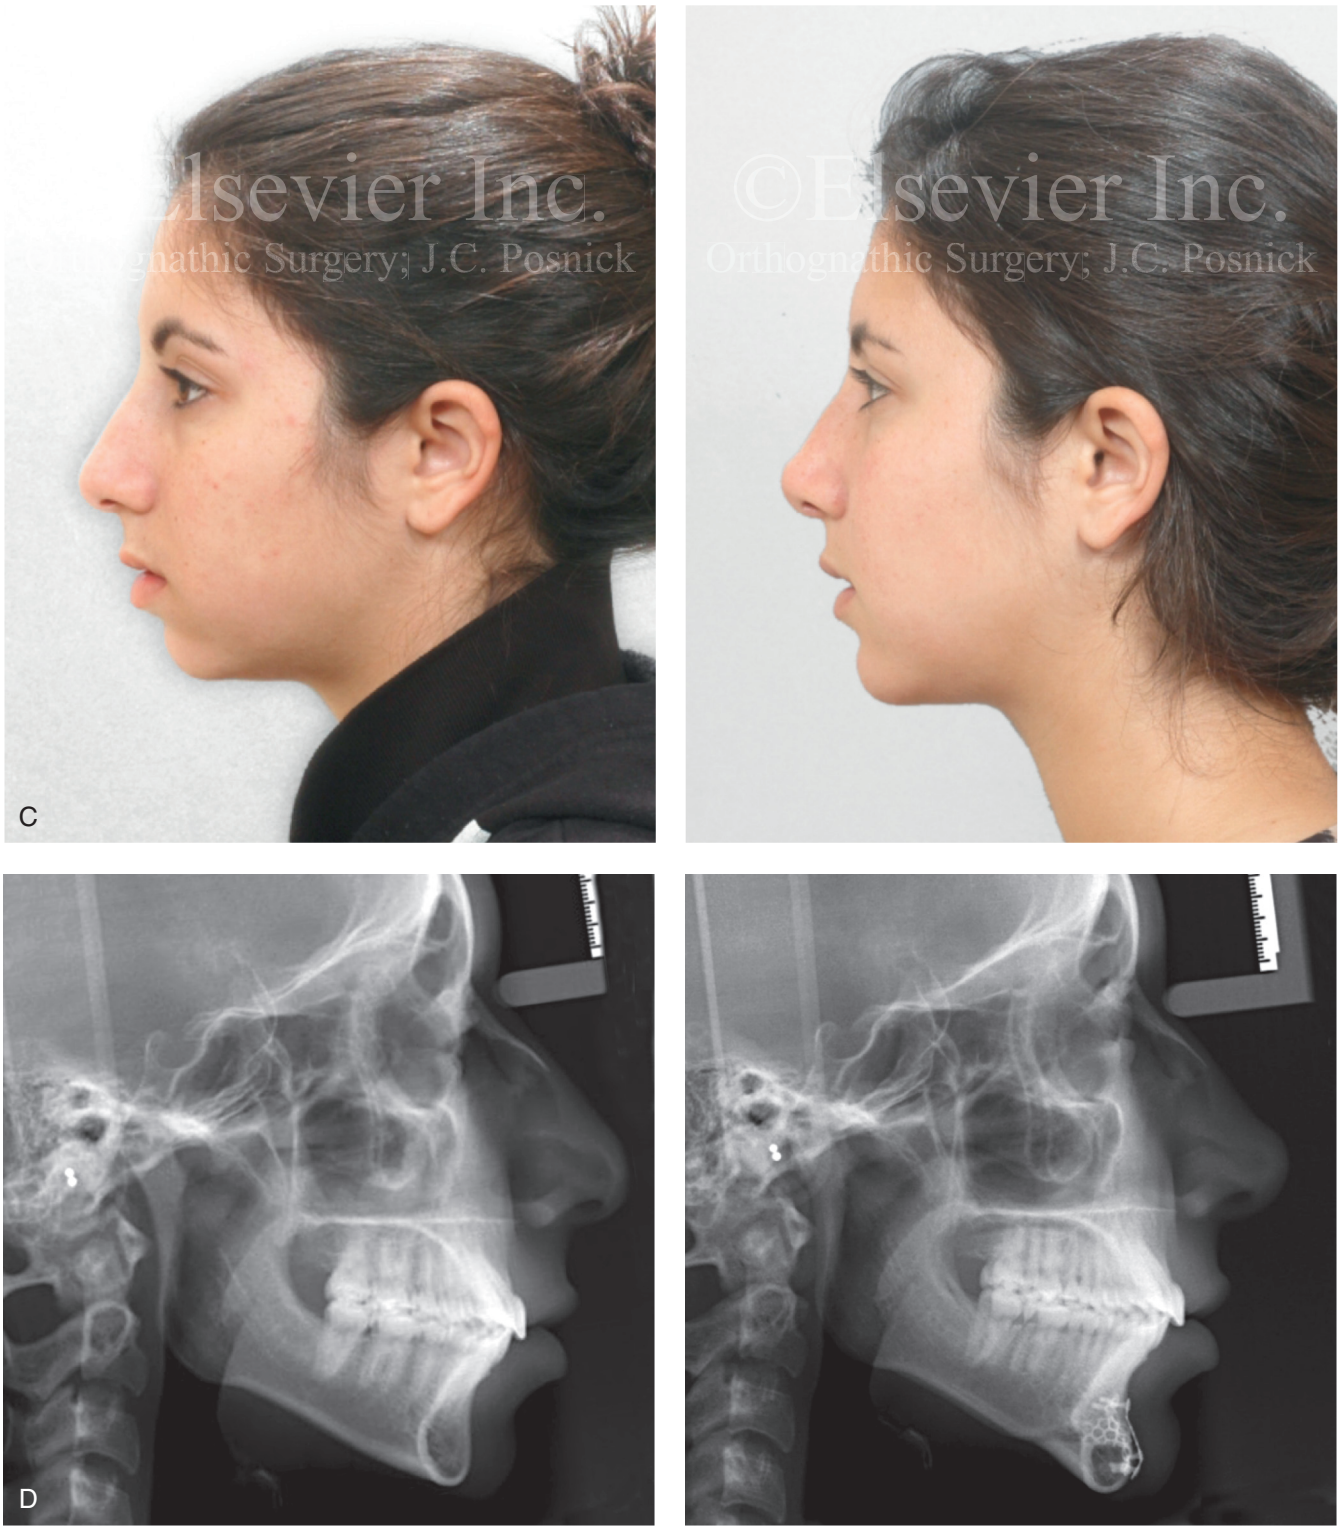
• **Figure 37-1** A 29-year-old woman arrived to discuss her chin aesthetics. During the mixed dentition, she was recognized as having mandibular deficiency and a constricted maxillary arch width. At that time, she underwent growth-modification techniques, including the use of headgear. She also underwent rapid palatal expansion followed by compensatory orthodontic mechanics to neutralize the occlusion, but this resulted in proclination of the incisors. A retrusive profile and a dual bite remained. She recently underwent the placement of an extended silastic chin implant but without fixation by another surgeon. Aesthetic modification of the anterior maxillary dentition was also completed by a restorative dentist. She is displeased with the cosmetic facial results of a deepened labiomental fold, a mobile chin implant, and a "button" appearance during lip closure. There is a dual bite with Class II malocclusion in centric relation. **A,** Oblique and frontal facial views after chin implant placement. **B,** Profile facial view and lateral cephalometric radiograph 6 months after chin implant placement.



• **Figure 37-2** A 17-year-old boy arrived with his father for the evaluation of a "weak chin" and requested chin augmentation. He had undergone orthodontic treatment with the establishment of a satisfactory occlusion that required minimal dental compensation. He agreed to undergo osseous genioplasty (horizontal advancement) to resolve the chief complaint. **A,** Profile views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Lateral cephalometric radiographs before and after reconstruction.

• **Figure 37-3** A 16-year-old girl arrived with her mother and requested a cosmetic rhinoplasty to reduce the dorsal hump and to improve the drooped nasal tip seen in profile. She also had a lifelong history of nasal obstruction. Evaluation confirmed the aesthetic nasal needs as well as sagittal deficiency of the chin. She agreed to undergo septorhinoplasty and osseous genioplasty. The rhinoplasty included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage) and tip maneuvers (modification of lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and the reduction of the inferior turbinates. Osseous genioplasty included horizontal advancement. **A,** Profile facial views before and after reconstruction. **B,** Oblique facial views before and after reconstruction.

• **Figure 37-4** A 17-year-old girl arrived with her mother and requested a cosmetic rhinoplasty to reduce the dorsal hump and to improve the drooped nasal tip seen in profile. She also had a lifelong history of nasal obstruction. Evaluation confirmed the aesthetic nasal needs as well as sagittal and vertical deficiency of the chin. She agreed to undergo septorhinoplasty and osseous genioplasty. The rhinoplasty include nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage) and tip maneuvers (modification of lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and the reduction of the inferior turbinates. Osseous genioplasty included horizontal advancement and vertical lengthening with interpositional grafting (bloc hydroxyapatite). **A,** Frontal views in repose before and after reconstruction. **B,** Oblique facial views before and after reconstruction.



• **Figure 37-4, cont'd** **C,** Profile facial views before and after reconstruction. **D,** Lateral cephalometric radiographs before and after surgery.

• **Figure 37-5** An 18-year-old girl arrived with her parents and requested a cosmetic rhinoplasty and a chin implant. She hoped for a smaller nose, a reduction of the dorsal hump, and a stronger profile. She also had a history of nasal obstruction after a sports injury earlier during her life. Examination confirmed mild sagittal deficiency of the mandible but with a functional occlusion and minimal dental compensation after earlier orthodontic treatment. She agreed to undergo septorhinoplasty and osseous genioplasty. The patient's nasal procedures included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage); tip maneuvers (modification of lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; the reduction of the inferior turbinates; and osseous genioplasty with horizontal advancement. **A,** Frontal views in repose before and 8 years after reconstruction. **B,** Oblique facial views before and 8 years after reconstruction.

• **Figure 37-5, cont'd C,** Profile views before and 8 years after reconstruction. **D,** Lateral cephalometric radiographs before and 8 years after reconstruction.

among the facial structures that should be taken into consideration.[1-3,51,52,60,69,95,118] Critical decisions with regard to where to position the chin through osseous genioplasty are made when viewing the patient "face to face" from varying perspectives in repose and during broad smile in the clinic setting.[4,16,124,126]

Biologic Foundation of Osseous Genioplasty

When carrying out an osseous genioplasty, a horizontal osteotomy below the roots of the anterior teeth and the mental foramen on either side is completed. After osteotomy, the distal segment of the chin remains attached to a musculoperiosteal pedicle. Healing is optimal when the circulation of blood to bone and its enveloping soft tissue is continuously maintained. In 1988, Bell and colleagues completed microangiographic and histologic studies in adult rhesus monkeys that indicated that an intraoral pedicled flap that involved an osteotomy of the inferior mandibular border maintains circulation and osseous viability after manipulation and repositioning of the chin segment.[106] According to Bell's experimental work, circulation to the dental pulp should not be discernibly affected during the process.

Frequent Patterns of Chin Deformities

Horizontal Chin Deficiency with or without Vertical Discrepancy

Contemporary maxillofacial surgeons now recognize that individuals who are seeking a "stronger chin" (i.e., horizontal

projection) frequently also have disproportions in the vertical dimension of their face.[23,33,45,59,61,77,88,89,92,116,120,123,127,131] Studies suggest that approximately 40% of individuals with horizontal (sagittal) chin deficiency have a decreased lower anterior facial height (i.e., short face growth pattern) (Figs. 37-4, 37-6, and 37-7). It is also known that another 25% of these will have the other extreme of an increased lower anterior facial height (i.e., long face growth pattern) (Figs. 37-8 through 37-11). In either case, the bony chin dysmorphology will also result in soft-tissue abnormalities (distortions) of the labiomental fold. This often includes a deep labiomental angle in those with a short face growth pattern and a flat labiomental fold in those with a long face growth pattern. Fifty percent of individuals with a horizontally deficient chin will have an Angle class II malocclusion, which is indicative of mandibular retrusion. Forty percent will have previously undergone orthodontic camouflage treatment in an attempt to mask their micrognathia (see Fig. 37-1). Incisor flaring will have resulted from the orthodontic camouflage approach that attempted to neutralize a Class II excess overjet malocclusion as an alternative to a more biologic correction of the mandibular deficiency through orthognathic surgery. Some of these individuals will have also undergone chin implant augmentation, often with a suboptimal result (see Fig. 37-1, 37-7, and 37-9).

A pleasing labiomental fold is an essential component of optimal lower face aesthetics. A strong correlation exists between the lower anterior facial height and the labiomental fold morphology. Individuals with decreased lower anterior facial height in combination with a retrusive-appearing chin tend to have an exaggerated and excessively deep labiomental fold with acute angulation between the lower lip and the soft-tissue chin pad (i.e. primary mandibular deficiency or maxillomandibular deficiency; see Figs. 37-4, 37-6, and 37-7). Individuals with increased lower anterior facial height in combination with a horizontally deficient chin are likely to have a labiomental fold that is flattened and effaced, with poor fold definition, excess mentalis strain, and difficult lip closure (i.e., long face growth pattern). The long face growth pattern classically consists of vertical excess of the maxillary and mandibular alveolar regions. This is combined with mandibular retrognathia and an anterior open-bite Class II malocclusion (see Figs. 37-8 and 37-9).

Rosen and others have pointed out that many individuals with mandibular deficiency and decreased lower anterior facial height who have a functional occlusion are unwilling to undergo an orthognathic correction and may opt for a compromise approach to at least achieve some aesthetic advantage (Figs. 37-12 through 37-17).[88-93] An osseous genioplasty to simultaneously vertically lengthen and horizontally advance the chin will generally achieve a degree of improved lower facial height and chin projection while reducing the deep labiomental fold. When this compromise is undertaken, no improvement in any baseline malocclusion or any significant opening of the airway should be expected. From an aesthetic perspective, it is essential to prevent an operated look when choosing a chin-only approach. This aesthetic error can be limited by avoiding the temptation to fully correct a moderate to severe mandibular deficiency through an isolated chin procedure (see Figs. 37-13 and 37-15).

In the individual with a functional occlusion, a retrusive chin and an increased lower anterior facial height (i.e., long face growth pattern), the surgical camouflage approach will be different than what is used for the patient with a short face growth pattern, as described previously. As an aesthetic compromise, it will be an advantage to vertically shorten and horizontally advance the chin (see Fig. 40-9). This will at least marginally decrease the mentalis strain to improve the ease of lip closure and also to enhance the appearance of the lower face (see Fig. 37-11).

Note: There are some patients with the long face growth pattern who do not have a long chin as part of their dysmorphology. These individuals do not have a flat labiomental fold, and they should not undergo a camouflage chin-only procedure consisting of horizontal advancement and vertical shortening as described previously.

To review, when evaluating a "weak" profile, it is important to consider not only the horizontal (sagittal) position of the chin but also the vertical dimension (excess or deficiency). In addition, it is essential to analyze the maxillomandibular proportions of the face (i.e., any existing jaw deformity) and the alignment of the teeth in the alveolar bone (e.g., dental compensation such as incisor flaring). Only after all facial and dental aspects are evaluated will the ideal treatment be understood and any reasonable compromise options be rationally considered in the light of their shortcomings.

Horizontal Chin Prominence and Associated Vertical Discrepancy

Individuals who present with a prominent pogonion are likely to have disproportions of the lower anterior facial height (i.e., the vertical dimension), which in turn affect labiomental fold morphology.[6,64,99,135] When an individual presents with a prominent pogonion and asks for a chin reduction only, he or she will likely not be pleased with the aesthetic result if this limited request is honored.

A commonly seen pattern of jaw deformity is maxillary deficiency in combination with relative mandibular excess (i.e., skeletal Class III growth pattern; see Chapter 20). This often presents in association with a vertically long (i.e., as measured in millimeters from the mandibular incisor edge to the menton height) and protrusive (i.e. forwardly projected) chin (Fig. 37-18). These individuals generally benefit from Le Fort I advancement with or without simultaneous vertical lengthening and clockwise rotation. Mandibular

Text continued on p. 1595

• **Figure 37-6** A 24-year-old woman arrived for evaluation. She had previously undergone four bicuspid extractions and orthodontics to neutralize her occlusion during her high school years. Analysis confirmed a short face growth pattern that accounted for her apparent large nose, weak profile, obtuse neck chin angle, and edentulous look. She agreed to a combined orthodontic and surgical approach. The patient's surgery included maxillary Le Fort I osteotomy (horizontal advancement, vertical lengthening, and clockwise rotation) with interpositional grafting; sagittal split ramus osteotomies (horizontal advancement and clockwise rotation); and osseous genioplasty (vertical lengthening and minimal horizontal advancement) with interpositional grafting. Minimal change in the occlusion was required (see Fig 23-3). **A,** Frontal views in repose before and after treatment. **B,** Oblique facial views before and after treatment.

• **Figure 37-6, cont'd** **C,** Articulated dental casts that indicate analytic surgical planning. **D,** Lateral cephalometric radiographs before and after treatment.

• **Figure 37-7** A 37-year-old man was referred with a request to have a chin implant removed because he was displeased with the aesthetic results. When he was 20 years old, he underwent chin augmentation with a silicone implant in an attempt to camouflage his small lower jaw profile. Ten years later, he underwent four bicuspid extractions and orthodontic alignment to improve his occlusion. He had also undergone a septorhinoplasty procedure, but he was still experiencing continued difficulty breathing through the nose. During evaluation by this surgeon, he was recognized as having a short face growth pattern with decreased lower anterior facial height and limited facial projection. There was an accentuated labiomental lip curl and a "button" appearance to the chin. It became clear during a discussion that the patient suffered with snoring, restless sleeping, and excessive daytime fatigue. An attended polysomnogram confirmed a respiratory disturbance index of 16 events/hr, with desaturations of up to 89%. A titration study confirmed the need for 12 cm of water pressure to reduce the respiratory disturbance index to 3 events/hr. The use of continuous positive airway pressure was attempted but found to be uncomfortable and difficult for the patient to use. **A,** Frontal views with smile before and after surgery. **B,** Profile views before and after surgery.

• **Figure 37-7, cont'd** Consultations with a sleep specialist, an otolaryngologist, and an orthodontist confirmed the advantage of an intranasal and orthognathic surgical approach. The patient agreed to perioperative orthodontics and surgery to improve the airway and facial appearance. His procedures included maxillary Le Fort I osteotomy (horizontal advancement +9 mm, vertical lengthening +5 mm), with interpositional grafting; bilateral sagittal split osteotomies of the mandible (horizontal advancement +12 mm); removal of the chin implant; osseous genioplasty (horizontal advancement and vertical lengthening) with interpositional grafting; reduction of the inferior turbinates; redo septoplasty; and an anterior approach to the neck (cervical flap elevation, defatting, and vertical platysma muscle plication). As a result of the procedures, the patient experienced relief of his snoring, improved quality of sleep, diminished daytime fatigue, and improved breathing during the day. Six months after surgery, he underwent an attended polysomnogram that indicated a normal sleep study with no snoring or apnea events (see Fig. 26-10). **C,** Articulated dental casts that indicate analytic surgical planning. **D,** Lateral cephalometric radiographs before and after surgery (note the preoperative chin implant).

• **Figure 37-8** A 21-year-old college graduate arrived for surgical evaluation. Her history and physical examination confirmed lifelong nasal obstruction, lip incompetence, difficulty chewing, and frequent speech articulation errors. Facial aesthetic concerns include a weak chin, a gummy smile, lip strain, and the impression of having a "big nose." The patient had been under an orthodontist's care since the mixed dentition and through her high school years. Growth modification attempts followed by rapid palatal expansion and full bracketing with four bicuspid extractions were unsuccessful to close the anterior open bite. Early periodontal and dental deteriorization were evident. Further evaluations were carried out by a speech pathologist, an otolaryngologist, and a periodontist; in addition, a fresh look was taken at this patient's orthodontic needs. Orthodontic dental decompensation in combination with orthognathic and intranasal surgery was chosen. The simultaneous procedures that were carried out included Le Fort I osteotomy in segments (horizontal advancement, vertical shortening, counterclockwise rotation, arch expansion, and correction of the curve of Spee); sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring (see Fig. 21-5). **A,** Frontal views in repose before and after reconstruction. **B,** Profile views before and after reconstruction.

• **Figure 37-8, cont'd** **C,** Articulated dental casts that indicate analytic model planning. **D,** Lateral cephalometric radiographs before and after surgery.

• **Figure 37-9** A 21-year-old college graduate arrived for surgical evaluation. Her history and physical examination confirmed lifelong nasal obstruction, heavy snoring, lip incompetence, difficulty chewing, and frequent speech articulation errors. Facial aesthetic concerns included a weak chin, a gummy smile, and the impression of having a "big nose." She had been under an orthodontist's care from the mixed dentition through her high school years. Growth modification followed by rapid palatal expansion and full bracketing with attempted closure of the anterior open bite were attempted, without success. She had undergone a chin implant in an attempt to improve the profile, but this was also suboptimal. Further evaluations were carried out by a speech pathologist and an otolaryngologist, and a fresh look was taken at this patient's occlusal/dental needs. Orthodontic decompensation in combination with orthognathic and intranasal surgery was chosen. The simultaneous procedures that were carried out included Le Fort I osteotomy in segments (horizontal advancement, vertical shortening, counterclockwise rotation, arch expansion, and correction of the curve of Spee); sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); removal of the chin implant; osseous genioplasty (vertical shortening and horizontal advancement); and septoplasty, inferior turbinate reduction, and nasal floor recontouring. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 37-13** A 27-year-old Indian woman arrived and requested of a reduction rhinoplasty and a chin implant to treat her perceived "big nose" and "small chin." Analysis confirmed maxillomandibular sagittal deficiency that was treated during her teenage years with compensatory orthodontics to neutralize the occlusion. There was marked procumbency of the maxillary and mandibular anterior dentition but with adequate tooth and gingival show, without lip incompetence and with good to the periodontium. The nasal aesthetic unit had thick skin but satisfactory proportions. The patient lacked lower anterior facial height and facial projection, especially at the pogonion. She was treated with an osseous genioplasty (vertical lengthening and limited horizontal advancement) and interpositional bloc hydroxyapatite grafting. **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction.

• **Figure 37-14** A woman in her early 20s arrived for the evaluation of her facial aesthetics. She had a developmental jaw deformity that was characterized primarily by mandibular deficiency and a lifelong history of obstructed nasal breathing. During her teenage years, she underwent an orthodontic camouflage approach that included maxillary bicuspid extractions with anterior dentition retraction to achieve an improved occlusion. She perceived a "big nose" and a "small chin" and requested reduction rhinoplasty and a chin implant. She refused redo orthodontics and an orthognathic correction (see Chapter 19). A compromise was agreed to that included open rhinoplasty and osseous genioplasty. The patient's rhinoplasty included nasal osteotomies (in-fracture and straightening); dorsal reduction (bone and cartilage); and tip maneuvers (modification of lower lateral cartilages and septal cartilage caudal strut grafting). Osseous genioplasty included vertical lengthening with interpositional bloc hydroxyapatite grafting and minimal horizontal advancement. **A,** Frontal views with smile before and after reconstruction. **B,** Oblique facial views before and after reconstruction.

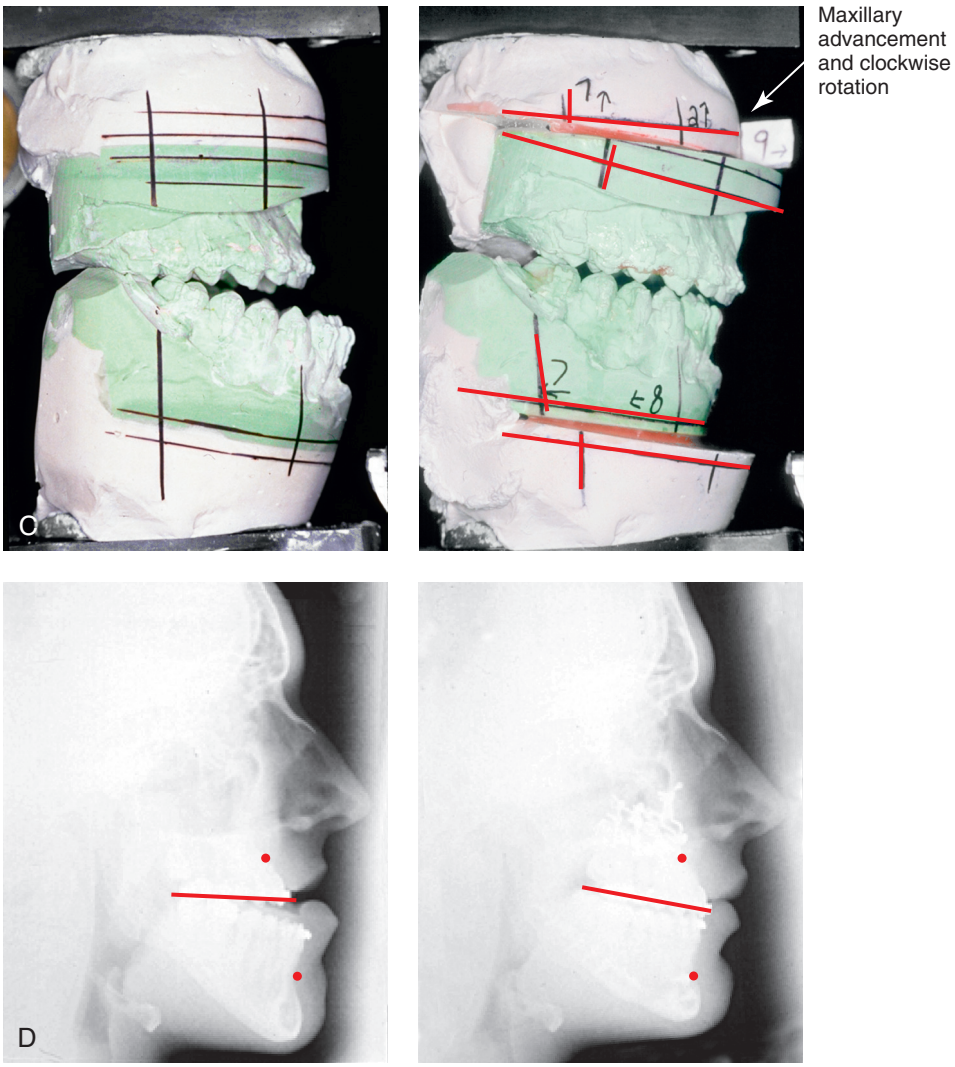
• **Figure 37-18** A 17-year-old high school student was referred by his orthodontist for surgical evaluation. His maxillary deficiency and mandibular excess Class III negative overjet anterior open-bite malocclusion required orthodontics and jaw surgery. Because the patient had a lifelong history of nasal obstruction and consistent physical findings, intranasal procedures were also required. With orthodontic dental decompensation complete, the patient's surgery included maxillary Le Fort I osteotomy (horizontal advancement, anterior vertical lengthening, and clockwise rotation); sagittal split ramus osteotomies (set-back); osseous genioplasty (vertical reduction); and septoplasty and inferior turbinate reduction. **A,** Frontal views before and after treatment. **B,** Profile views before and after treatment.



• **Figure 37-18, cont'd C,** Articulated dental casts that indicate analytic model planning. **D,** Lateral cephalometric radiographs before and after treatment.

ramus osteotomies are also carried out with limited or no set-back at the incisors but with clockwise rotation to diminish projection at the pogonion. In this case, lower-face aesthetics are often further enhanced via an osseous genioplasty with vertical reduction and minimal sagittal change.

A second frequent pattern of presentation is an individual with a chin that appears prominent in profile because the mandible is overly closed (i.e., short face growth pattern). In these patients, the vertical height (in millimeters) from the mandibular incisal edges to the menton is deficient. With this dentofacial deformity, both horizontal and vertical deficiency of the maxilla and the mandible (i.e., decreased lower anterior facial height and limited facial projection) are present (see Chapter 23). A "pseudoprotrusion" of the chin will result. A patient who asks for a chin set-back only to manage his or her short face (i.e., maxillomandibular deficiency) is unlikely to be pleased with the aesthetic result if this request is honored. In this case, reestablishing the preferred vertical and horizontal dimensions of the face requires a Le Fort I osteotomy with horizontal advancement, vertical lengthening, and, often, clockwise rotation. The mandible—which is also horizontally and vertically deficient—requires sagittal split ramus osteotomies and reorientation to match the new maxillary position. The chin region also benefits from a change in shape. This is accomplished through an oblique osteotomy of the chin with clockwise rotation (i.e., downward and backward positioning of the pogonion) while maintaining contact and pivoting at the posterior osteotomy line. The interpositional gap is grafted with allograft, autograft, or bone substitute, and the chin segment is fixed in place with plates and screws (see Figs. 37-6 and 37-7).

All of these facial aspects must be considered before embarking on any treatment of the chin region if a favorable result and a satisfied patient are to be expected.

Chin Asymmetries

Asymmetries of the chin relative to the face are most frequently encountered in association with specific syndromes and other conditions such as hemifacial microsomia, hemimandibular elongation, hemimandibular hyperplasia, or a condyle fracture sustained during childhood with resultant ipsilateral mandibular undergrowth (Fig. 37-19). For individuals who present with the chin shifted to one side, aesthetic assessment of the entire face, including the soft tissues and the skeletal structures, should be undertaken. Consideration is given to both the lower facial skeleton (i.e., the maxilla, the mandible, and the chin region) and the upper facial skeleton (i.e., the cranial vault, the zygomas, the orbits, and the nasal bones). The chin region may be asymmetric or disproportionate, or it may simply appear to be so as a result of maxillary or mandibular malposition. In several of the conditions mentioned, the extent of actual chin asymmetry is much less than that of the mandible and maxilla. When indicated, a Le Fort I osteotomy and sagittal

• **Figure 37-19** A 16-year-old boy who had sustained a fracture of the right condyle of the mandible during his early childhood presented with resulting facial asymmetry. He previously underwent years of orthodontics to neutralize the occlusion, which also resulted in loss of labial bone along the anterior mandibular teeth. He then underwent an orthognathic approach that included Le Fort I osteotomy (cant correction); left sagittal split ramus osteotomy; reconstruction of the right condyle–ascending ramus with a costochondral graft; and an osseous genioplasty (correction of vertical and horizontal asymmetry) (see Fig. 35-8). **A,** Frontal facial views with smile before and after reconstruction. **B,** Oblique facial views before and after reconstruction. *A, from Posnick JC: Management of facial fractures in children and adolescents,* Ann Plast Surg *33:442-457, 1994.*

split ramus osteotomies of the mandible with three-dimensional repositioning will greatly improve the chin symmetry. A separate osteotomy to reposition the chin region is also generally required to simultaneously correct disproportion of the lower third of the face.

Osseous Genioplasty: Surgical Technique (Videos 11 and 12)

- Attention is turned to the facial vestibule of the chin. The lower lip is stretched outward to allow for visualization of the mental nerve through the mucosa on each side. In the depth of the vestibule, an incision is made with a Bovie electrocautery device or a knife (no. 15 blade) just through the mucosa from cuspid region to cuspid region, stopping just short of the visualized mental nerve on each side (Fig. 37-20, *A*). The center two thirds of the incision is next extended down to bone. A full cuff of mucosa and muscle is maintained adjacent to the attached gingiva of the anterior teeth; this should allow for adequate layered wound closure of the muscle and mucosa without periodontal sequelae.
- Dissection with an elevator exposes the anterior surface of the chin although not completely to the inferior border of the central chin. The dissection continues laterally and remains inferior to the mental nerve, with lateral exposure to the inferior border of the mandible. There is no need to dissect above the mental nerve on either side. If 360-degree dissection around the nerve is completed, it is more likely that the nerve will be excessively stretched or avulsed.

G

• **Figure 37-20, cont'd**

- A small S-shaped Tessier chin retractor is placed on each side inferior to the mental nerve and laterally to the inferior border. A sterile pencil is used to mark the location of the oblique osteotomy ((see Fig. 37-20, *B*). This should be planned sufficiently below the dental roots and the mental foramen on each side. The exact location of the osteotomy will depend on the presenting chin morphology and the planned reconstruction (i.e., vertical reduction or lengthening and the extent of horizontal advancement).
- With the use of an oscillating saw (i.e., a thin fan blade on a long shaft), a vertical groove is made in the midline across and perpendicular to the proposed horizontal osteotomy. This will help to maintain vertical orientation after the osteotomy and before fixation (see Fig. 37-20, *C*).
- A drill hole is placed in the midline within the distal chin (see Fig. 37-20, *C*). Later, a screw (1.7 mm in diameter and 8 mm in length) will be partially inserted and used as a retractor. The screw is usually not placed in the distal chin until the osteotomy is completed. It will then be held with a wire twister that is used as a retractor to facilitate the repositioning and orientation of the distal chin unit.
- The oblique osteotomy of the chin is initiated in the central portion with the use of an oscillating saw (i.e. wide fan blade on a short shaft). The use of this saw and blade to initiate the osteotomy helps to maintain orientation and to limit canting (see Fig. 37-20, *D*).
- Using a reciprocating saw with a short blade and then with a longer blade is helpful to complete the lateral aspects of the osteotomy and to go through the depth of the bone on each side (see Fig. 37-20, *E*). An osteotome may be inserted with a twisting motion to complete the osteotomy separation (see Fig. 37-20, *E*).
- When vertical shortening of the chin is planned, there are two options. If only limited shortening is required in combination with horizontal advancement, it may be preferred to use a rotary drill with a watermelon bur to remove bone height at the osteotomy line. If a more significant vertical reduction is planned, a second parallel osteotomy (for ostectomy) is completed through the proximal chin (below the dental roots) using a reciprocating saw with a straight blade on a long shaft. Any lateral–inferior bony irregularities are also removed using a rotary drill with a watermelon bur to limit palpable or visible step-offs.
- The distal chin is held in the desired position by the assistant to the surgeon with the use of the wire twister secured to the positioning screw. The surgeon contours each titanium plate across the osteotomy site and then secures each with screws (1.7 mm in diameter and 4 mm in length). Typically, either a three- a four-hole straight plate is contoured with the ends placed on either side of the osteotomy. The superior screw is usually placed in between and inferior to the lateral incisor and canine on each side (see Fig. 37-20, *F*). With the chin secured in its new location, the positioning screw is removed.
- If significant vertical lengthening of the chin is planned, an interpositional graft (e.g., autograft, allograft, bloc hydroxyapatite) is crafted and placed in the gap. The graft fills the central gap between the fixation plates. I do not find it necessary to place graft in the lateral aspect of the gaps. An additional plate and screws are generally placed vertically in the midline across the osteotomy site and directly over the graft (see Chapter 18 and Fig. 37-20, *G*).

Achieving Favorable Chin Aesthetics

Establishing preferred aesthetics in the chin region is heavily dependent on the surrounding structures. The variables include the following: 1) maxillomandibular morphology; 2) the position of the teeth within each arch; and 3) the soft-tissue envelope that overlies the skeletal structures.

Preferred *maxillomandibular morphology* is primarily dependent on the following: 1) facial height; 2) sagittal projection; and 3) A-point–to–B-point relationships when viewing the facial profile and the natural head position. Ideally, the positioning of the teeth within the alveolar bone establishes the preferred *incisor inclination,* which is an important component of perioral aesthetics. The *overlying soft-tissue envelope* will be distorted by either maxillomandibular skeletal or dental disharmony. Common patterns of soft-tissue distortions may include either lip strain with labiomental effacement (i.e., long face growth pattern) or a full flaccid lower lip with a deep labiomental fold (i.e., mandibular deficiency growth pattern).

Morphology of the chin aesthetic unit is an important aspect of facial aesthetics. The essential components of chin morphology include *vertical height, horizontal projection,* and the *surface contour of the pogonion.* When considering the chin aesthetic unit, an assessment of the individual's lateral cephalometric radiograph is useful. As stated, if the vertical height of the chin is too long, lip incompetence and an overly effaced lip–chin soft-tissue drape will result. If the vertical height of the chin is too short, there will be a flaccid lower lip, a deep labiomental curl, and a "button" appearance to the soft tissues.

Riolo's table of normative cephalometric values confirms that the mean vertical height of the chin (i.e., the mandibular incisal edge to the menton) is approximately 42 mm (±2.7 mm) for females and 49.4 mm (±2.9 mm) for males.[83A] These measurements are a useful benchmark from which to judge the preferred vertical height of the individual's chin.

The extent of preferred horizontal chin projection at the pogonion should be with reference to the B-point. When viewing an individual's lateral cephalometric radiograph taken in the natural head position and with the incisors upright (with or without the need for orthodontics) and with the maxillomandibular vertical height and horizontal projection being proportionate (with or without the need

for orthognathic surgery), the pogonion should not project more than 3 mm to 5 mm anterior to the B-point. If the pogonion projects too far in front of the B-point, the overly prominent chin is unattractive. If the pogonion does not project enough in front of the B-point, then a "weak" chin will be apparent in profile.

At times, the surface contour of the anterior bony chin will be unattractive. Two common patterns of chin-surface dysmorphology include either an *overly pointed pogonion* or *bifid bony morphology* (i.e., prominent lateral tubercles). Direct recontouring of the exposed chin surface with a bur on a rotary drill can be carried out to improve either of these surface irregularities. When indicated, this is accomplished simultaneously with an inferior border osteotomy to also alter the vertical height and horizontal projection of the chin.

In review, errors concerning chin aesthetics are more likely when maxillomandibular morphology and incisor inclination are not fully considered. Attempting to compensate for the unfavorable positioning of either the maxillomandibular complex or the teeth is responsible for much of the observed patient dissatisfaction after a chin procedure. The common error in these circumstances is to either use an osseous genioplasty to project the pogonion too far in front of the B-point or to place a "too-large" chin implant with a resulting unnatural look. Either of these techniques is likely to be more unattractive than the presenting "weak" chin.

Avoiding Pitfalls during Chin Surgery

The chin is one of the most visually prominent facial features, and its role in facial appearance has been recognized since antiquity. It may seem to be an easy structure to alter, but focusing on the chin without fully considering the associated facial dysmorphology (e.g., the skeleton, the dental and soft tissues) may have unexpected and unwanted effects on overall aesthetics. The basic surgical technique of osseous genioplasty is reviewed earlier in this chapter. It is also illustrated in Figure 37-20 and can be seen on (**Videos 11 and 12**). Avoiding pitfalls during the aesthetic evaluation of the patient's chin and during the surgical execution of an osseous genioplasty is essential to the achievement of a favorable outcome.*

1. When assessing a chin that is considered to be either retrusive or protrusive, place the patient in the natural head position and the mandible in the rest position (i.e., with the condyles seated and with normal freeway space between the teeth in each arch). The lips should be relaxed and separated. By assessing the face in this way, you are likely to unmask any baseline dentofacial deformity (e.g., short or long face growth pattern) and to gain a more accurate impression of any true chin disproportion.
2. The experienced surgeon will rely heavily on the direct visual examination to evaluate overall facial proportions and any notable mirror-image asymmetries that involve (but are not limited to) the chin region. Without protractors or rulers, the absence of Euclidean proportions can usually be discerned. Confirmation of the clinician's aesthetic impressions may then be clarified through either anthropometric surface measurements or cephalometric radiographic analysis, as indicated.
3. The theoretic advantage of an alloplastic (chin implant) genioplasty is that it is a procedure that is seemingly easier to execute and often considered less invasive by the patient. It has the disadvantage of being primarily effective only for a mild anteroposterior deficiency of the chin, and it generally requires an external facial scar. It will have a higher incidence of infection than a chin osteotomy, and such an infection may even occur years later.[34,35,41,49,82,121,125] In addition, there may be underlying bony erosion from the implant over time, and the individual can never be without at least some concern about trauma to the chin. Alternatively, the osseous genioplasty is versatile in all three planes and has proven and long-lasting results without concerns about infection, bony erosion, a shift in position, or the need for limited physical activities after initial satisfactory healing has occurred.
4. When completing the intraoral incision and the soft-tissue dissection to expose the surface of the bony chin, avoid subperiosteal dissection above the mental neurovascular bundle to limit the extent of nerve contusion and stretching and the chance of avulsion from the mental foramen. The mucosal incision should be deep in the vestibule to leave a full cuff of mucosa and muscle for ease of two-layer closure and to limit periodontal sequelae.
5. When lengthening the chin, an oblique osteotomy with the interpositional placement of a graft (e.g., allogenic or autogenous bone, porous bloc hydroxyapatite) is generally preferable to the placement of a chin implant (as mentioned in point 3; see Fig. 37-20, *G*).
6. When vertical reduction and posterior set-back are indicated, the vector of reduction and set-back should generally follow the long axis of the chin prominence. This will avoid step-offs at the junction of the chin osteotomy and the inferior border of the mandible and limit suboptimal aesthetics as a result of the "bunching" of the soft tissues (see Fig. 37-18).
7. When using a reciprocating saw to complete the posterior (lateral) aspect of the oblique chin osteotomy, the inferior border may unknowingly remain partially intact. When this happens, there is a tendency for the uncontrolled fracture of the chin to be more posterior than desired. This can result in an

*References 5, 12, 15, 19, 35, 38-40, 42, 47, 48, 55, 58, 62, 63, 71, 74, 76, 78, 81, 93, 94, 96, 102, 103, 110, 111, 119, 122, 134

uneven aesthetic result, and it is avoided by carefully completing the lateral and posterior osteotomy before the "splitting" of the chin (see Fig. 37-20, *E*).

8. When completing a vertical reduction and advancement genioplasty, limit significant step-offs at the junction of the chin osteotomy and the inferior border of the mandible to avoid a palpable ridge or an unattractive "hourglass" appearance to the inferior border of the mandible. A continuous inferior border of the mandible is less likely to accentuate jowling. A significant ridge at the osteotomy site may be prevented by extending the chin osteotomy more posterior (i.e., as far back as first molar); by not "overadvancing" the chin (i.e., in profile, the soft tissue of the chin should not be anterior to the lower lip); and by recontouring any significant step-offs using a rotary drill with a watermelon bur before securing the chin in its new location.
9. When an alloplastic chin implant has failed and requires removal (i.e., as a result of suboptimal aesthetics, infection, bony erosion, or a shift in implant position), chin morphology is generally best restored with a vascularized osseous genioplasty rather than another avascular implant. Unfortunately, the implant will have stretched the overlying soft tissues, resulting in ptosis and possible muscle dysfunction when it is removed. If the chin implant was composed of non-porous material (e.g., Silastic), then a fibrous capsule will have formed, which adds to the residual soft-tissue deformity. Reassessing the overall maxillofacial morphology is essential before proceeding with further chin surgery. A baseline maxillo-mandibular dysharmony may be present and require reconstruction to best achieve patient satisfaction (see Figs. 37-1, 37-7, 37-9, and 37-10).
10. When the surface contour of the chin is severely dysmorphic (i.e., overly pointed or bifid), direct bur recontouring using a rotary drill with a watermelon bur is the preferred approach. This does not negate the simultaneous completion of an oblique osteotomy for the three-dimensional repositioning of the remaining chin unit. Adequate circulation to the distal chin is maintained through the genioglossus and geniohyoid muscle attachments to the genial tubercle.
11. When completing an oblique osteotomy of the chin, the temporary placement of a screw in the distal chin (i.e., one that is only halfway screwed in) that is then clamped with a wire twister (i.e., to be use used as a handle or retractor) is helpful for ease of positioning of the chin before osteotomy fixation (see Fig. 37-20, *C* and *F*).
12. Marking the midline of the bony chin with a small vertical notch perpendicular to the proposed horizontal osteotomy helps with the maintenance of chin symmetry before the placement of plate and screw fixation (see Fig. 37-20, *C*).
13. Adequate fixation of the distal chin across the osteotomy site is reliably carried out with a limited volume of small titanium plates and screws. The type and extent of screws and plates used will vary in accordance with patient-specific fixation needs and surgeon preferences (see Fig. 37-20, *F* and *G*).

Complications and Unfavorable Results

Although the majority of patients who have undergone an osseous genioplasty state that they would do it again, complications and suboptimal results will always occur in a minority of cases.*

Infection

Infection occurs among less than 1% of patients who have undergone an osseous genioplasty. The routine use of prophylactic antibiotics to cover both oral flora and skin organisms is useful to limit this complication. When an avascular implant is placed to augment the chin (rather than a chin osteotomy being performed), a higher rate of infection would be expected. This is especially true for non-porous implants that are not stably fixed to the underlying bone.

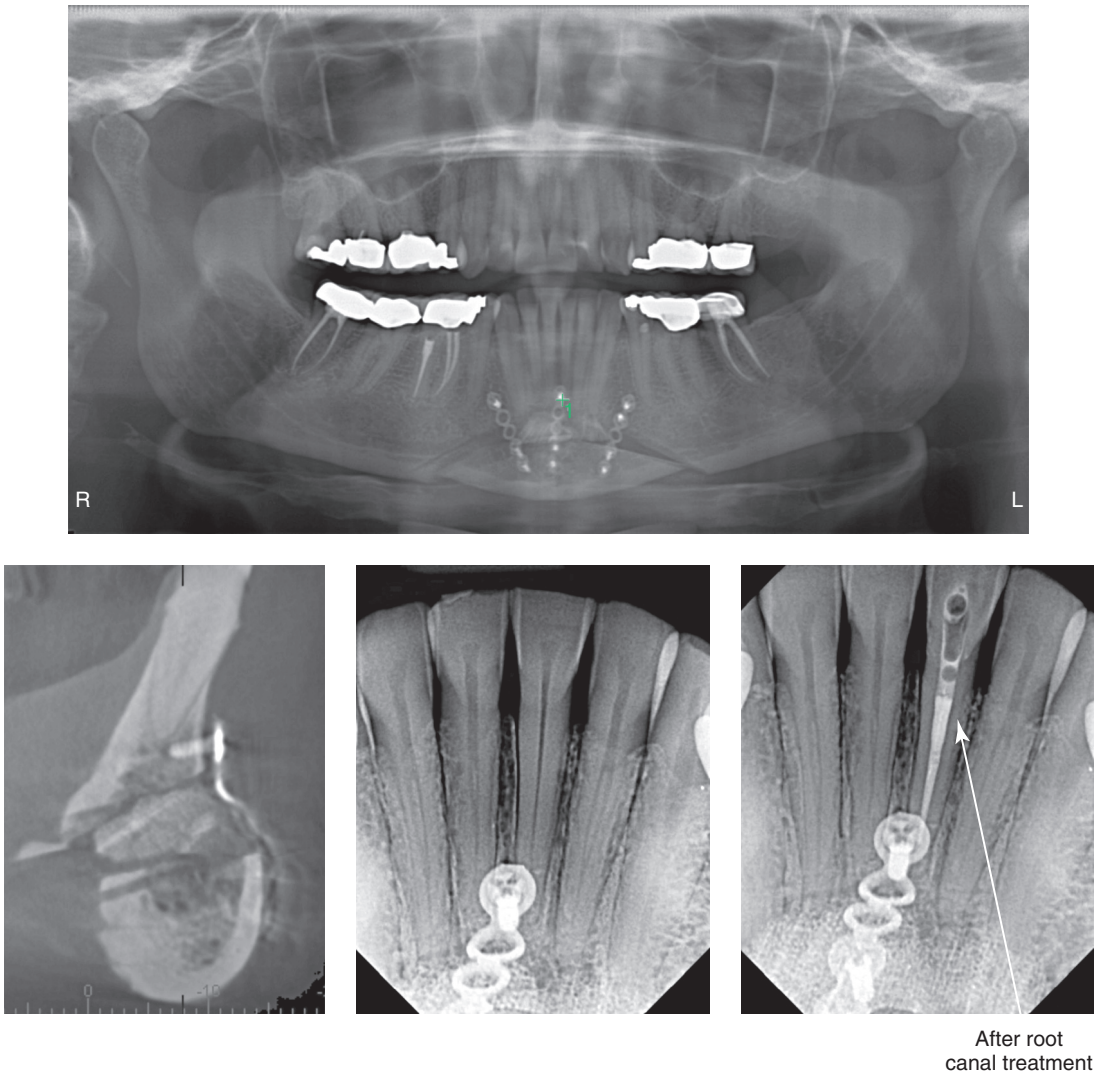
Altered Sensibility

The mental nerve is at risk of injury in association with an osseous genioplasty. The mental nerves will always be stretched when the soft-tissue dissection and retraction is carried out for exposure of the chin. The observed loss of sensibility to the lip–chin region early after surgery is usually temporary. The potential for cutting the mental nerve during the soft-tissue vestibular incision is limited by taking care during the lateral aspect of the incision. The nerve can also be avulsed from the mental foramen during retraction at the time of osteotomy. When determining a location for the osteotomy, remember that the nerve dips below the mental foramen posteriorly. According to the literature, as many as 10% of patients may experience a degree of permanent loss of sensibility in the distribution of the mental nerve on one or both sides as a result of genioplasty.

Wound Complications

The osseous genioplasty is completed through an intraoral vestibular incision. To limit wound-healing complications, the incision is made in the depth of the vestibule. Maintenance of the attached gingiva and a full cuff of mucosa and muscle adjacent to the cervical margins of the teeth best ensures a relaxed wound closure in two layers (i.e., the muscle and the mucosa). This will minimize wound dehiscence, muscle dysfunction, and chin ptosis and limit mucogingival problems. Placing the soft-tissue incision too close

*References 7, 10, 11, 17, 18, 20, 24, 25, 29, 32, 34, 49, 53, 54, 65, 72, 73, 75, 80, 82, 85, 98, 100, 113, 114, 117, 121, 133, 136, 137



• **Figure 37-21** An oblique osteotomy of the chin was carried out (vertical lengthening and horizontal advancement) with interpositional hydroxyapatite grafting. Postoperative radiographs indicate the closeness of the screw fixation to the lateral incisor (1.7-mm diameter and a 4-mm length). Darkening of the crown indicates pulpal injury. Root canal therapy and internal bleaching of the involved tooth were carried out.

to the teeth can negatively affect wound healing and result in scar bands and periodontal sequelae (e.g., mucogingival pull).

Injury to the Teeth

The location of the chin osteotomy should be based on the patient's chin morphology. The review of the patient's radiographs (e.g., lateral cephalometric, Panorex) will confirm the anatomy of the anterior teeth and the location of the mental foramen. Injury to the teeth at the time of osteotomy is not common, but it can occur. Dental injury may also occur as a result of the placement of the fixation screws, but this is also not common. If dental injury is suspected, evaluation by the patient's dentist or referral to an endodontist is recommended. Discussions among the surgeon, the dentist, and the patient are essential, because root canal therapy or other forms of treatment may be indicated (Fig. 37-21).

Patient Dissatisfaction

Patient dissatisfaction after an osseous genioplasty will generally revolve around facial aesthetics. This is best avoided via the following means:

1. Accurate preoperative facial and dental assessment by the surgeon and then discussion with the patient of the following: 1) the surgeon's findings; 2) the patient's goals; 3) any patient-specific biologic limitations (e.g., soft tissues, skeletal, dental); 4) any baseline head and neck dysfunction that may be related to the

chin (e.g., breathing, lip competence); and 5) the surgeon's overall recommendations
2. A clear understanding among all parties of the operative objectives and any compromises in treatment that have been jointly agreed upon
3. The meticulous execution of the procedures by the surgeon with the patient under controlled anesthesia and with proper instrumentation and assistance
4. At set time intervals after surgery, a discussion with the patient about the results achieved and any shortcomings perceived

Alloplastic Chin Augmentation

Successful chin implants are primarily placed to address mild deficiencies in the sagittal dimension at the pogonion and any limited hypoplasia immediately lateral to the symphysis.[128,129] Depending on the philosophy and skill of the surgeon, some vertical lengthening may also be possible.[130] Complaints after alloplastic chin augmentation are not infrequent, which may explain their decreased use by board-certified surgeons over a recent 10-year time frame.* Available statistics from the American Society of Aesthetic Plastic Surgeons confirm an 85% drop in the number of chin implants that were placed between 1997 and 2009 (i.e., 11,000 implants were placed in 1997, whereas 1700 were placed in 2009).[101] Although individuals often present with the specific complaint of a "weak chin" and with a seemingly simple request for a "chin implant," they frequently have a combination of microgenia, mandibular deficiency, and additional associated maxillofacial dysmorphology. A complete systematic soft-tissue and skeletal facial evaluation is required. The surgeon may choose not to discuss associated baseline maxillomandibular skeletal deformities either as a result of a lack of knowledge (i.e., an incomplete diagnosis) or because the patient or family "only requested a chin implant." In either case, after sagittal chin augmentation, a dissatisfied patient may express bewilderment with the result and at a minimum demand implant removal (see Figs. 37-1, 37-7, 37-9, and 37-10). When indicated, counseling the patient about the preferred orthodontic and orthognathic approach versus camouflage genioplasty alone is advised.

When the facial aesthetic analysis indicates that an implant is an acceptable alternative, a customized porous polyethylene chin augmentation with screw fixation is generally preferred.[104,128-130] Silicone (i.e., Silastic) implants heal with a surrounding fibrous capsule. Porous polyethylene implants heal with fibrous tissue in-growth into the open pores. The placement of an appropriately shaped implant with stable fixation will limit the risk of displacement, infection, and erosion of the underlying bone. The obliteration of dead-space gaps (i.e., between the implant and the skeleton) by custom contouring the implant and when applying compressive fixation screws before wound closure is essential. To review, experienced surgeons generally recommend the following: 1) placing a chin implant through a submental incision without intraoral exposure; 2) using an implant of porous material that is customized; and 3) applying stable screw fixation to increase success and limit complications.[128-130]

Despite the apparent technical ease of placing an alloplastic implant, a disproportionate number of repetitive problems seem to occur after a chin implant.[11,24,57,97] A common clinical scenario involves sagittal augmentation with an implant that is excessive in size and that does not address vertical aspects or associated jaw deformity. In these cases, it is generally not just the patient who perceives that the implant is too big; it is hard for the surgeon and other observers at conversational distance to deny the unfavorable aesthetic result, and thus surgeons are forced to honor their patients' request for implant removal. Unfortunately, depending on the material used, the implant may have caused capsule formation, splaying of the mentalis muscles, and stretching of the overlying soft-tissue envelope. After removal of the "too-large" implant, soft-tissue contracture may occur, which looks even worse with dynamic function (i.e., the soft-tissue "balling up" effect). If mentalis muscle dysfunction remains, there may be unattractive sagging (ptosis) of the soft tissues. Removing the implant and simply placing a smaller one has a low probability of satisfying the patient's concerns. Facial reassessment may clarify other skeletal deformities (e.g., primary mandibular deficiency, maxillomandibular deficiency, long face growth pattern) that account for the suboptimal result. Many times, after implant removal, a chin osteotomy with three-dimensional repositioning with or without combined orthognathic procedures will give the best result.

Frequent sequelae include improper initial positioning of the chin implant (i.e., not directly over pogonion) and inadequate fixation with lateral or superior shifting. These conditions may result in suboptimal aesthetics, erosion of the underlying bone, or compression of the mental nerve with dysesthesia of the lip–chin region. A late trauma event involving an otherwise initial satisfactory implant may lead to swelling and then infection. Late infection as a result of either bacteremia with secondary implant seeding or an adjacent dental infection can also occur. Management generally requires drainage, the removal of the implant, and the use of antibiotics. After resolution, further reconstructive options can be considered.

Conclusions

An osseous genioplasty can be a useful technique for the enhancement of facial aesthetics. Before an isolated genioplasty procedure can be considered, a thorough facial aesthetic and head and neck functional assessment—followed by a frank discussion with the patient and the family about

*References 8, 11, 14, 21, 24, 26, 27, 37, 41, 46, 50, 56, 57, 67, 68, 70, 72, 84, 86, 87, 97, 107-109, 115, 132

the ideal treatment and any compromised treatment agreed to—is essential. A review of the risks, possible complications, and hoped-for benefits of a chin reshaping procedure should result in a high degree of patient satisfaction. To limit the occurrence of a dissatisfied patient outcome, the setting of realistic and agreed-upon objectives is essential. The meticulous execution of the procedure by the surgeon with the patient under controlled anesthesia and with proper instrumentation and assistance further ensures success.

Patient Education Materials

Osseous Genioplasty (Chin Reshaping) Surgery

Many people are motivated to alter their chins when they see themselves in profile. For example, when the chin is small, it may undermine the entire face and make the nose look larger and more conspicuous. An osseous genioplasty is a procedure that is often carried out to reshape or change the size, projection, or appearance of the chin. The chin region may be surgically changed with regard to its length, projection, or symmetry.

An osseous genioplasty may balance your profile by enhancing or diminishing chin prominence in relationship to the nose, jaws, and lips. Strengthening the chin will tend to tighten the skin of the neck and generally maintain or restore a more youthful appearance. The surgical reshaping of the chin is carried out either as an isolated procedure or as part of other facial surgery (e.g., orthognathic procedures, rhinoplasty, neck lift). The procedure usually requires 1 hour and is carried out with the patient under anesthesia. The incision that is used to gain access to the chin is made on the inside of the lower lip. Depending on other procedures that are carried out simultaneously, most people return to work after 1 week.

INSTRUCTIONS FOR OSSEOUS GENIOPLASTY SURGERY

The purpose of these instructions is to help you prepare for and recover from your operation with as little discomfort and inconvenience as possible.

Preoperative Instructions

1. Do not take any aspirin, aspirin-containing, or aspirin-like products (e.g., Advil) for at least 2 weeks before surgery. Aspirin and aspirin-like products tend to increase bleeding during surgery and bruising postoperatively.
2. Be sure that you do not smoke and that there are no nicotine products in your bloodstream for at least 3 weeks before and 2 weeks after surgery. Nicotine in the bloodstream jeopardizes wound healing. Smoke that is chronically ingested by the lungs may also result in pulmonary complications that will hinder optimal healing.
3. Do not eat or drink anything after midnight the night before surgery, not even a sip of water. You may brush your teeth, but do not swallow the water.
4. Starting 2 days before surgery, we request that you shampoo your hair and shower at least once per day. The morning of surgery, you may also shower and shampoo your hair again.
5. We will give you a prescription for pain control and another for antibiotics. You may wish to fill them before the date of surgery.
6. Be sure to make arrangements for someone to accompany you home after surgery, because you will not be allowed to drive.

Postoperative Instructions

1. A cold compress applied in the neck and chin region should reduce swelling and discomfort for the first 24 to 36 hours after surgery. However, this is of little value after that time.
2. Keep the head of your bed elevated when resting and sleeping for the first week after surgery.
3. You may shower and shampoo your hair the day after surgery. Do not be afraid to wash your face and neck.
4. After discharge from the hospital, eat lightly (mostly liquids) and advance to a soft diet during the first week until further instructions are given.
5. You should begin brushing your teeth the day of surgery. Brush your upper teeth in the regular way and your lower teeth (including the anterior teeth) carefully and slowly. Do not brush the incision.

Continued

6. Keep your level of physical activity to a minimum, get lots of rest, and do not do anything that requires more than limited physical exertion during the first week after surgery. You will gradually increase your activity level, but no sports or exertional exercise are allowed for 5 (five) weeks from the date of surgery. Ask your surgeon for specific instructions with regard to physical activity.
7. Do not consume beverages that contain alcohol or drive a motorized vehicle while taking prescription pain medications.
8. When you are at home, you should take the prescribed pain medication as needed. Tylenol may be substituted when your pain has diminished. Avoid taking aspirin or aspirin-like products for an additional 2 weeks after surgery. Take the antibiotic medication as directed until the supply is exhausted.
9. Call the office for an appointment to see your surgeon on the date specified on your discharge instructions. If there are any concerns, contact your surgeon's office at any time, day or night. After hours, the answering machine will advise you about how to proceed.

Jeffrey C. Posnick, DMD, MD
Director, Posnick Center for Facial Plastic Surgery

Consent for Osseous Genioplasty Surgery

_____ **INSTRUCTIONS**

Initial here This is a document that has been prepared to help your surgeon educate and inform you about your chin reshaping (genioplasty) surgery and its risks as well as alternative treatment options. It is important that you read this document carefully and completely. Please initial each section on each page to indicate that you have read and understand it. In addition, please sign the consent for surgery on the last page as proposed by your surgeon.

_____ **INTRODUCTION**

Initial here Many people are motivated to alter their chins when they see themselves in profile. For example, when a chin is small, it may undermine the entire face and make the nose look larger and more conspicuous. Genioplasty is a surgical procedure that is often carried out to reshape or change the size, projection, or appearance of the chin.

Under anesthesia, in an operating room, a small incision is made on the inside of the lower lip. Then, with the use of specialized instruments, the bone of the chin is cut and then repositioned or reshaped in accordance with your specific needs as discussed with your surgeon.

Genioplasty can balance your profile by enhancing or diminishing chin prominence in relationship to the nose, jaws, and lips. Strengthening the chin may tighten the skin of the neck and generally result in a more attractive appearance. The surgical reshaping of the chin is carried out either as an isolated procedure or as part of other facial surgery (e.g., orthognathic procedures, rhinoplasty, neck lift). The surgery usually requires about 1 hour to complete. Most people return to work 1 week after surgery.

_____ **ALTERNATIVE TREATMENT**

Initial here Alternative forms of management include not doing anything to your chin at all. Some individuals may consider a chin implant option; this involves the placement of artificial material (i.e., a chin implant) directly over the surface of your bone. Risks and potential complications are also associated with this and other alternative forms of treatment. These are all issues to consider in detail before you select the approach that best suits your overall needs.

_____ **RISKS OF SURGERY**

Initial here Every surgical procedure involves a certain amount of risk. An individual's choice to undergo a specific procedure is based on the comparison of the risk to potential benefit. Although the majority of patients do not experience the complications detailed below, you should discuss each of these items with your surgeon to be sure that you understand the risks, potential complications, and consequences of the chin reshaping surgery planned for you.

_____ **SURGICAL ANESTHESIA**

Initial here The use of both local and general anesthesia involve risk. Complications and injuries are possible with all forms of anesthesia and sedation.

_____ **INFECTION**

Initial here Infection is not common after chin reshaping surgery. Treatment with antibiotics will begin just before surgery and is continued afterward surgery. If an infection does occur, additional treatment (e.g., a change in antibiotics, drainage, other procedures) may be necessary.

_____ **SCARRING**

Initial here Although good wound healing after the procedure is expected, abnormal healing or unattractive scars may occur within the skin, the deeper structures, and the mucous membranes. Additional treatment or procedures may be helpful to treat scarring or gingival (gum) problems.

_____ **ALTERATION OF FACIAL SENSIBILITY**

Initial here With a genioplasty procedure, the mental nerve is at risk for injury. Such an injury may result in diminished sensation of the lower lip, the skin of the chin, the gums around the anterior teeth, and the anterior teeth themselves. Gradually over the course of 6 to 12 months, the feeling improves and generally returns to close to normal. Approximately 10% of the time, a degree of permanent sensory loss in the lower lip, chin, gums, and teeth remains.

_____ **INJURY TO ADJACENT TEETH**

Initial here During the genioplasty procedure, injury to the roots of the anterior teeth or interference with the circulation (blood flow) to the dental and bone segments can occur. Devitalization (nerve damage) of the teeth, which may then require a root canal procedure, can occur. Infrequently, the teeth may be injured by the fixation screws. It is possible (but unlikely) that the loss of teeth may occur and later require additional treatment. These are not common events, but they must be mentioned as possible occurrences.

_____ **DISSATISFACTION WITH FACIAL APPEARANCE**

Initial here An individual's dissatisfaction with his or her facial appearance after genioplasty surgery is not common, but it can occur. Despite your surgeon's best efforts, on occasion, this type of surgery may result in visible deformities, asymmetries, or structural malposition. You may be disappointed if the results of the chin surgery do not meet your expectations. Additional treatment and procedures may be possible should the results be considered unsatisfactory.

Continued

_____ **FACIAL ASYMMETRY**

Initial here The human face is normally asymmetric. There can also be variation from one side of the face to the other with regard to the results achieved with a chin reshaping procedure. Additional surgery may be possible should the extent of asymmetry be of concern.

_____ **MEDICATIONS**

Initial here Medications, prescription drugs, and anesthetics, may cause drowsiness and a lack of awareness and coordination, which can be increased by the use of alcohol or non-prescription drugs. Your surgeon advises you not to operate any vehicles, automobiles, or other potentially hazardous devices while taking such medications and until you have achieved full recovery from the effects of these substances. We ask that you not drive yourself home after discharge from the hospital or to and from office appointments initially after surgery.

_____ **HEALTH INSURANCE**

Initial here Most health insurance companies exclude coverage for changing the shape of the chin (genioplasty) or for any complications that may arise from this surgery. Please carefully review your health insurance subscriber-information to clarify these issues.

_____ **FINANCIAL RESPONSIBILITIES**

Initial here The cost of surgery involves several charges for the services provided, including the fees charged by your surgeon (i.e., surgeon's fees); the cost of surgical supplies, laboratory tests, and the use of the operating room (i.e., hospital charges); and the cost of anesthesia (i.e., anesthesiologist's fees). Depending on whether the cost of surgery is covered by your medical insurance plan, you will be responsible for necessary copayments, deductibles, and all other charges that are not covered. Additional costs may occur should complications or an unfavorable result develop from the surgery. Any secondary surgeries and all charges involved with revision procedures (i.e., surgeon's fees, hospital charges, and anesthesiologist's fees) would also be your responsibility.

_____ **DISCLAIMER**

Initial here Informed-consent documents are used to communicate information about the proposed surgery and to disclose risks and alternative forms of treatment. The informed-consent process attempts to define principles of risk disclosure that should generally meet the needs of most patients in most circumstances.

Since every patient is unique, this informed-consent document should not be considered all-inclusive with regard to defining methods of treatment and potential risks encountered. Your surgeon will provide you with additional written and verbal information that is based on all of the facts of your particular case and the current state of medical knowledge.

Informed-consent documents are not intended to define or serve as the standard of medical care. Standards of medical care are determined on the basis of all of the facts involved in an individual case and are subject to change as scientific knowledge and technologic advances and practice patterns evolve.

It is important that you read the above information carefully and have all of your questions answered by your surgeon before signing the consent form on the next page.

CONSENT FOR OSSEOUS GENIOPLASTY SURGERY

1. I hereby authorize my surgeon, _____, and such assistants as may be selected by my surgeon to perform the following procedure(s):

   _____

   _____

2. I have received, read, and understand the following information sheets:
   - Osseous Genioplasty Surgery
   - Book Chapter about Genioplasty
   - Consent for Osseous Genioplasty Surgery
3. I recognize that, during the course of the operation, unforeseen conditions may necessitate different procedures then those listed above. I therefore authorize my surgeon, _____, and my surgeon's assistants or designees to perform such other procedures that are in the exercise of professional judgment necessary and desirable. The authority granted under this paragraph shall include all conditions that require treatment and that are not known to my surgeon at the time the procedure is begun.
4. I acknowledge that no guarantee has been given by anyone with regard to the results that may be achieved by the procedures to be carried out.
5. I agree not to use alcoholic beverages and unprescribed drugs and to avoid all sports and water activities for at least 5 (five) weeks and then to resume them only after approval by my surgeon.
6. I consent to the photographing of me (head and neck region) before, during, and after surgery. These photographs may be used by my surgeon for medical, scientific, or educational purposes now and in the future.
7. I agree to cooperate completely with the recommendations of my surgeon and to provide all medical and dental information about myself while I am under my surgeon's care. I realize that a lack of same could result in less than optimal care.
8. I consent to the disposal of any body tissues or medical devices that may be removed.
9. **THE FOLLOWING INFORMATION HAS BEEN EXPLAINED TO ME IN A WAY THAT I UNDERSTAND:**
   - THE PREVIOUSLY DESCRIBED PROCEDURES TO BE UNDERTAKEN
   - ALTERNATIVE PROCEDURES AND METHODS OF TREATMENT THAT I HAVE DECIDED AGAINST
   - THE SPECIFIC RISKS AND POTENTIAL COMPLICATIONS OF THE PROCEDURES THAT I PLAN TO UNDERGO

I CONSENT TO THE PROCEDURES AND THE ABOVE LISTED ITEMS (1 THROUGH 9). I AM SATISFIED WITH THE EXPLANATION GIVEN TO ME.

Nasal Surface Anatomy

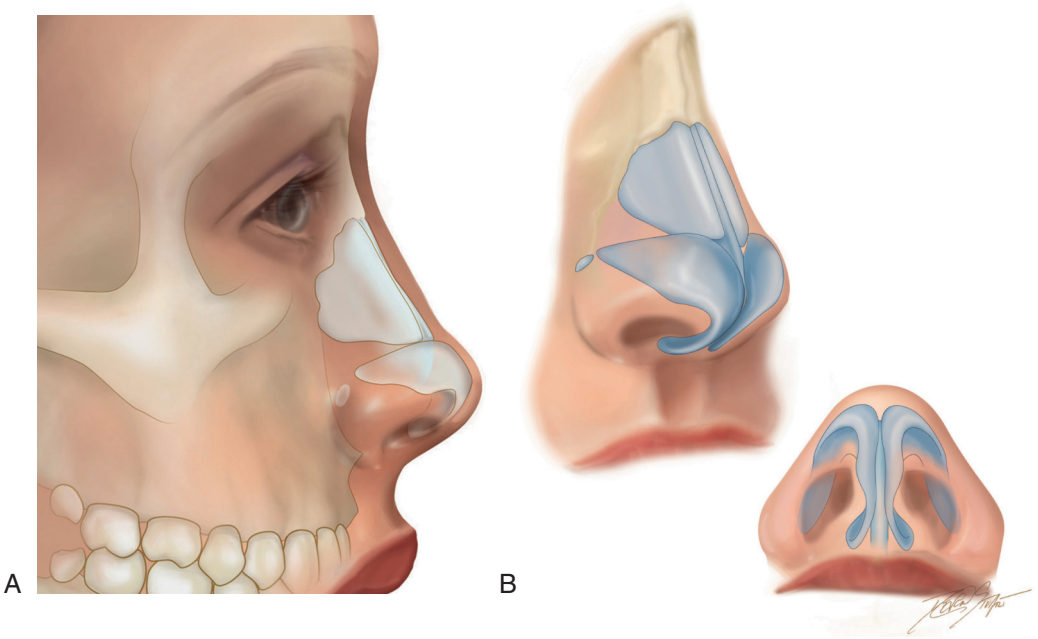
The external nose may be described as consisting of three parts: the osseocartilaginous vault, the lobule/tip, and the base (Fig. 38-1).

The *osseocartilaginous vault* consists of the bony vault (the nasal bones, the nasal process of the frontal bones, and the nasal process of the maxilla) and the cartilaginous vault (the upper lateral cartilages [ULCs] and the dorsal aspect of the cartilaginous septum). The transition from bony to cartilaginous dorsum is called the *keystone area.*[49] The caudal aspects of the nasal bones overlap the cephalic portions of the ULCs in the keystone area. The width of the nasal bones and ULCs is greater in the keystone area than at either the radix or the supratip regions.

Aesthetically, the dorsum of the nose is analyzed with regard to its height or anterior projection and its width and shape. Ideally, the dorsum of the nose, when viewed in profile, should be straight or slightly concave. The *nasofacial angle* is a soft-tissue measurement from the nasion to the tip and from the nasion to the glabella and should be approximately 34 to 36 degrees. The width of the *dorsal lines of the nose* should be roughly equal to that of the philtral columns. The maximum width of the bony vault (i.e., the dorsal width) of the nose is ideally less than that of the medial intercanthal width.

The *lobule of the nose* encompasses the entire area that overlies the lower lateral cartilages (LLCs), whereas the *intrinsic nasal tip* represents the area between the nasal-tip–defining points and the area between the infratip breakpoint and the supratip breakpoint. The ideal *tip-defining points* are approximately 6 to 8 mm apart in females and 8 to 10 mm apart in males. The LLCs are key anatomic points of reference that define the *nasal tip*. They are subdivided into the *medial crus,* the *middle crus,* and the *lateral crus.* Of aesthetic importance are the angles formed by the junction of the crura; these include the *columella infratip breakpoint* (i.e., the middle crura–medial crura angle) and the *dome tip-defining points* (i.e., the middle crura–lateral crura angle).

The *columella* is a critical region and component of the nose. It must be in balance between the adjacent alar rims and the medial crura. It should also form an attractive angle with the upper lip (i.e., the *nasolabial* or *columella–labial angle*). If the columella is either retracted or demonstrating excessive show, it will be less attractive and benefit from change (i.e., augmentation versus reduction).



• **Figure 38-1 A,** Illustration of the soft tissues and skeletal anatomy of the nose as seen in profile view. **B,** Illustration of the skeletal anatomy of the external nose and the lower lateral cartilages as seen in three-quarter and worm's-eye views.

The thickness and *quality of the soft tissues over the nasal skeleton* have a significant impact on the appearance and will also affect the final result of a rhinoplasty. In most individuals, the skin is thickest in the supratip region; it thins over the domal area.

To the experienced clinician, the appearance of the external nasal anatomy will give an indication of the anatomic causes of subjective nasal airway obstruction.[249] Middle-vault collapse, pinched nasal sidewalls, asymmetric nostrils, and a crooked dorsum are all outward indications of obstructions to nasal airflow; this is discussed later in this chapter.

Classic Rhinoplasty Maneuvers

Classic rhinoplasty maneuvers include the following 1) nasal osteotomies (i.e., to reduce the nose's width, to straighten a crooked nose, and to close an open roof) 2) dorsal reduction (bone and cartilage) 3) the selective removal of cephalic portions of the lower lateral crura (maintenance of 6 mm of caudal rim) 4) suturing of the LLCs (i.e., interdomal and transdomal areas) and 5) augmentation with cartilage grafts (i.e., caudal strut graft, alar contour grafts, lateral crural strut grafts, shield tip graft, columellar tip graft, spreader grafts, dorsal strut graft).[47,51,69,93,138,142-144,182,207,219,237]

Grafts are indicated when other lesser maneuvers to improve the projection and definition of the nasal tip are not adequate.* When indicated, a graft that will be used to alter the nasal tip can be fashioned from removed quadrangular cartilage or from another source (e.g., the conchal floor, the rib cartilage).[201] A *caudal strut graft* remains the workhorse for the addition of support to weak LLCs and for the control and maintenance of the nasal tip position. The caudal strut graft also functions as a central scaffold on which the tip structures can be unified. When a *shield tip graft* is used, it is placed over the domes with the inferior margin extending to the mid columella. A shield graft is effective for increasing infratip lobular definition and projection. *Columellar tip grafts* extend superiorly and are often secured to the ULC above and the caudal margin of the medial crura below. They are more useful in thick-skinned individuals in whom there is an additional need to improve tip definition beyond the usual rhinoplasty maneuvers. In thin-skinned individuals, tip grafts are only used cautiously, because they may result in visible irregularities.

Interdomal sutures are placed in mattress fashion in the region of the middle crura.[89,98,199] This suturing technique is effective for reducing interdomal distance and thereby increasing tip projection and refinement. *Medial crural fixation sutures* are placed to unify the medial crura beneath the domes of the LLC and to reduce flaring. These sutures are typically placed after a caudal strut graft is secured. *Transdomal sutures* are placed in a horizontal mattress fashion and then across the dome of the middle crura. All of these suture techniques can be effective to alter the tip position, to narrow the distance between the tip-defining points, and to correct domal asymmetries.

Spreader grafts may be either horizontal or vertical, and they are used to correct deficiencies of the cartilaginous vault.[24,38,46,87,88,92,95,97,208,209,255] *Vertical spreader grafts* are generally paired and extend from just deep to and then flush

*References 6, 21, 23, 36, 46, 48, 53, 70, 79, 90, 96, 99, 100, 108, 135, 156, 169, 174, 235, 239, 241

with the nasal bones. They are secured on each side of the dorsal septum and then generally to the ULCs with sutures. The caudal end of each vertical spreader graft may continue beyond the septal angle and below the LLCs to elongate the nose and to derotate the tip. They are typically 15 to 20 mm in length and approximately 2 to 4 mm in width. A *horizontal spreader graft* is a single dorsal graft that is inset between the ULCs and that forms a "T" with the dorsal septum. Spreader grafts are used as a technique to prevent or correct the narrowing of the internal nasal valve, to preserve or correct the nasal dorsum or dorsal aesthetic lines, and to correct and stabilize a "crooked" dorsal septum.

There are four aspects of the *nasal base* that may be considered for surgical modification[5]:

1. Selective reduction of the caudal aspect of the quadrangular cartilage (septum) may be completed to limit columella show in profile. Augmentation of the deficient caudal septum may be required after overaggressive rhinoplasty or to reconstruct congenital deficiencies (e.g., Binder syndrome).
2. Modification of the anterior nasal spine may be carried out to alter the nasolabial angle or to augment a congenital deficiency (e.g., Binder syndrome).
3. Deepening of a high nasal floor and widening of narrow pyriform apertures by recontouring (e.g., using a rotary drill with a bur) may be indicated to improve the airway and to enhance aesthetics (i.e., in those with a long face growth pattern). Augmentation of this region may also be carried out to reconstruct a deficiency (e.g., Binder syndrome, alveolar clefting).
4. A cautious approach to excision of the alar rims (i.e., Weir excisions) may be performed to achieve a preferred interalar width (i.e., just less than the intercanthal width). It is preferred to accept a slightly increased interalar width rather than to end up with an "operated" look from either overresection of the rims or resulting scarring.

Facial versus Nasal Proportions and Effects on the Aesthetic Perspective

The surgeon must distinguish between the *aesthetics of the nose* (i.e., nasal proportions) and the *aesthetics of the face* (i.e., overall facial proportions) (Fig. 38-2).* Establishing the *Euclidean proportions* of the full face represents a different aesthetic objective than simply establishing pleasing proportions of the nose as an isolated aesthetic unit. The individual who is seeking rhinoplasty often perceives that his or her aesthetic objectives can be met by addressing the nose only. In these circumstances, after cosmetic rhinoplasty, the surgeon may be pleased with improvements in the nasal aesthetic unit, but the patient may express displeasure with the results. This will more frequently occur in the individual with either a long face growth pattern, a short face growth pattern, or an isolated sagittal mandibular deficiency growth pattern who perceives that he or she still has a "big" nose, even after rhinoplasty (Fig. 38-3). The patient may have initially sought out a cosmetic surgeon and requested a rhinoplasty with the goal of achieving a "smaller" nose. The surgeon may create a well-proportioned nasal aesthetic unit, but the nose may still remain "big" in proportion to the rest of the face. The surgeon may then be asked to revise the rhinoplasty to create a "smaller" nose.[192,193] When the surgeon further reduces the nasal bones and cartilage beneath the soft-tissue envelope, an "operated" look may result, and the overall facial proportions may move even further out of balance.

The Nasal Airway: Anatomy and Physiology

Symptomatic nasal obstruction is a condition in which the individual feels that he or she has inadequate nasal airflow. Although it is a subjective feeling, it should have a foundation in objective anatomic and physiologic findings (Fig. 38-4). Knowledge of both nasal anatomy and physiology is required for the accurate diagnosis and treatment of the subjective sensation of obstructed nasal breathing.*

Bony Anatomy

The *anterior (pyriform) aperture* generally represents the narrowest bony aspect of the nasal airway.[123] Its anatomic boundaries include the paired nasal bones (i.e., the nasal pyramid), which join to the ascending process of the maxilla laterally. The *bony floor of the nose* is formed by the superior aspect of the premaxillary alveolus anteriorly and the secondary palate posteriorly. The *anterior nasal spine* is in the anterior midline of the nasal floor, and the *posterior nasal spine* is in the posterior midline of the nasal floor. These spines provide the anterior and posterior limits of the inferior aspect of the cartilaginous and bony septum, respectively.

The *posterior (choanae) aperture* has a medial wall that is formed by the *vomer,* which is the posterior aspect of the nasal septum. The floor of the choanae is formed by the posterior aspect of the hard palate. The lateral walls of the posterior aperture are formed by each lateral maxillary process.

The *posterior inferior septum* is composed of the vomer, and it is contiguous with the *perpendicular plate of the ethmoid* superiorly. The anterior septum is composed of the

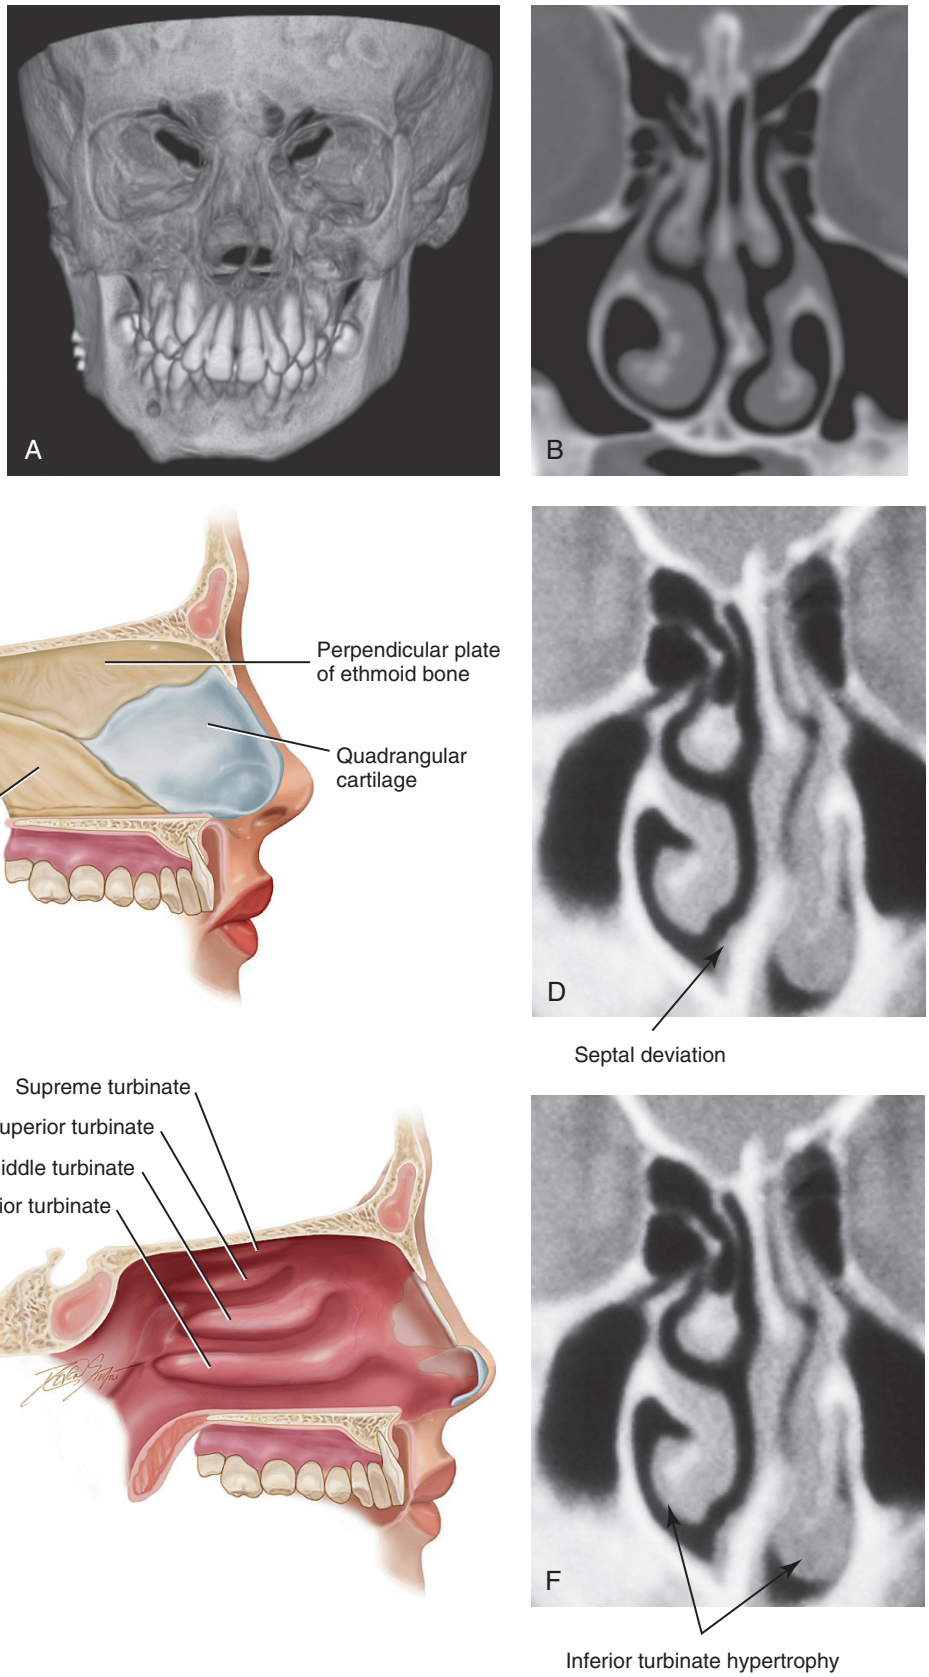
• **Figure 38-2 A,** Frontal and **B,** profile views of a well-proportioned face, including the underlying skeletal anatomy, are illustrated.

• **Figure 38-3** The clinician must distinguish between the aesthetics of the nose (i.e., the nasal aesthetic proportions) and the aesthetics of the face (i.e., the facial aesthetic proportions). Establishing the Euclidean proportions of the overall face represents a different aesthetic objective than simply establishing pleasing proportions of the nose as an isolated aesthetic unit. The individual who is seeking rhinoplasty often perceives that his or her objectives can be met by addressing the nose only. Errors in aesthetic judgment are especially frequent when viewing an individual with the following uncorrected issues: 1) a long face growth pattern (see Chapter 21); 2) a primary mandibular deficiency growth pattern (see Chapter 19); 3) a short face (maxillomandibular deficiency) growth pattern (see Chapter 23); or 4) a maxillary deficiency with a relative mandible excess growth pattern (see Chapter 20). Four case examples are shown to illustrate the importance of aesthetic perspective. **A,** A woman in her mid 20s with a long face growth pattern is shown before and after undergoing successful orthognathic surgery to correct facial disproportion. Before surgery, the nasal aesthetic unit was reasonably well proportioned but appeared "big" when viewing the face in profile. After successful orthognathic surgery, the same nose appears well proportioned with respect to the rest of the face. The procedures performed included Le Fort I osteotomy, sagittal split ramus osteotomies, and osseous genioplasty (see Fig. 21-5). **B,** A woman in her late 20s requested the evaluation of a "big" nose and a "small" chin. After successful orthognathic correction, which included sagittal split ramus osteotomies and osseous genioplasty the nose appears well proportioned with respect to the rest of the face (see Fig. 19-7).

Continued

• **Figure 38-3, cont'd C,** A teenage girl with a short face growth pattern (maxillomandibular deficiency with excess overjet) had previously undergone orthodontics to neutralize the occlusion. She complains of a "big" nose and a "small" chin. She is shown before and after successful orthognathic surgery that included Le Fort I osteotomy (horizontal advancement, vertical lengthening, and clockwise rotation), sagittal split ramus osteotomies (horizontal advancement, and clockwise rotation), and osseous genioplasty (vertical lengthening). After surgery, the nose no longer appears big and is well proportioned with respect to the rest of the face (see Fig. 23-2). **D,** A 20-year-old college student with a maxillary deficiency and a relative mandibular excess growth pattern arrived for a surgical evaluation with complaints of a "big" nose and "prominent" chin. He is shown before and after successful orthognathic surgery. The patient's procedures included Le Fort I osteotomy (arch expansion, horizontal advancement, vertical lengthening, and clockwise rotation) and sagittal split ramus osteotomies (clockwise rotation). After surgery, the nose no longer appears to be prominent, and the chin region of the lower jaw assumes improved proportions within the face (see Fig. 20-4).



• **Figure 38-4** **A,** A three-dimensional computed tomography (CT) scan view of a mixed-dentition skeleton with a deviated septum. **B,** A coronal CT view through the nasal cavity and maxilla demonstrates a deviated septum and enlarged inferior turbinates. **C,** A sagittal section through the nasal cavity and the maxilla is illustrated. The anatomy of the septum is highlighted. **D,** A CT scan through the nasal cavity (coronal cut) demonstrates a deviated septum. **E,** A sagittal section through the nasal cavity and the maxilla is illustrated. The anatomy of the turbinates is highlighted. **F,** A coronal CT view through the nasal cavity demonstrates a deviated septum and enlarged inferior turbinates.

quadrangular cartilage, which is contiguous with the bony septum.

Attached to the lateral nasal walls are three paired "scroll-like" bones that are known as the *turbinates.* The superior, middle, and inferior turbinates are composed of *conchal bones* that support the *erectile mucosal tissue* of the turbinates. Just inferior to each turbinate is a space called a *meatus.* Each of the paired sinus cavities drains into either the superior or the middle meatus region. The inferior meatus drains the *nasolacrimal duct.* The middle meatus provides the drainage pathway for the anterior ethmoid, maxillary, and frontal sinuses. The superior meatus is the drainage region for the posterior ethmoid and sphenoid sinuses. The majority of the air that passes through the nose is at a line below the middle turbinate.

Cartilaginous Anatomy

The cartilaginous septum joins to the bony portion of the septum (i.e., the vomer and perpendicular plate of the ethmoid) and the nasal crest of the maxilla inferiorly. The caudal aspect of the cartilaginous septum that joins to the maxillary crest does so through densely interwoven fibers of periosteum and perichondrium. The cartilaginous septum is called the *quadrangular cartilage* because of its geometric shape. Even small deviations or deflections of the septum can significantly alter nasal airflow. A frequent surgical procedure involves the removal of portions of the quadrangular cartilage that are obstructive to nasal airflow or for the purpose of grafting either the nasal tip or vault. During this procedure, it is important to maintain adequate dorsal and caudal struts of the quadrangular cartilage, which are responsible for the strength and support of the cartilaginous vault.

The cartilaginous anatomy of the nose also includes the *paired ULCs,* the *paired LLCs,* and the variable *sesamoid cartilages* (see Fig. 38-1). The ULCs are trapezoidal in shape and articulate with the nasal bones superiorly, with the quadrangular cartilage over the midline dorsum, with limited connections laterally to the bony pyriform aperture, and also to small sesamoid cartilages inferiorly. The LLCs connect to the ULCs superiorly via fibrous tissue. The LLCs are responsible for much of the form and shape of the nasal tip and the ala. Components of the LLC include the medial, middle, and lateral crura (see Fig. 38-4).

Intranasal Anatomy

Within the nose, sites of obstruction tend to occur at specific locations, including the *external nasal valves,* the *internal nasal valves,* the *turbinated cavities,* and the *posterior nasal (choanae) apertures* (see Fig. 38-4).

The *external nasal valve* is described as the area bounded by the caudal edge of the ULC superolaterally, the nasal ala and attachment of the lateral crus of the LLC laterally, the caudal aspect of the cartilaginous septum and the soft tissue of the columella medially, and the nasal sill and bony floor inferiorly. The size of the opening is variable and dependent on the shape, location, and strength of the bordering structures.

Generally, the site of greatest resistance to the entrance of air into the entire human airway is the *internal nasal valve.* Anatomically, the internal nasal valve is bordered superiorly by the ULC, medially by the cartilaginous nasal septum, laterally by the anterior aspect of the inferior turbinate, inferiorly by the nasal floor, and also laterally by the anteromedial aspect of the maxilla (i.e., the pyriform rim).

Mucosal Anatomy

The lining of the nasal cavity is composed primarily of epithelium. Along the superficial aspect of the external nasal valve, keratinized stratified squamous epithelium (i.e., skin) is present. Within the nose, the mucosal lining transitions from respiratory epithelium with goblet cells that secrete mucin to basal cells, columnar cells (ciliated and non-ciliated), and granule cells. Mucin glands are scattered throughout the nasal airway. The sinuses, in combination with the nasal cavity mucosa, produce between 1 and 2 liters of mucin each day. In the superior aspect of the nasal cavity are located specialized neuroepithelial cells that contain bipolar olfactory receptor neurons and mucin glands.

Nerve Supply

In addition to general sensory nerve supply through the first and second divisions of the trigeminal nerve, there is autonomic and sympathetic innervation to the nasal cavity.

Nasal Physiology and Function

The five major functions of the nose are *respiration, filtration, humidification, protection,* and *temperature regulation. Filtration* is accomplished through the vibrissae (located in the vestibule) and the mucosal cilia, which line the airway. *Humidification* and *temperature regulation* of the air are controlled by specialized vascular tissues that are regulated by sympathetic and parasympathetic nerve fibers. The capillary system is supplemented by venous sinuses that may constrict and result in enlargement, especially of each inferior turbinate.[103] *Protection* from bacteria and viruses is both mechanical and chemical. Chemical protection is provided by immunoglobulin A and muramidase, which are found in the mucus on the membranes of the nasal cavities. Mechanical clearing of trapped organisms is provided by the beating cilia, which move the mucous blanket into the nasopharynx every 20 minutes. During *respiration,* the nose resists the inspiration of air by providing almost 50% of the total airway resistance.

Airflow in the nasal cavity is very much related to resistance. The *airflow resistance* in the nasal cavity is

somewhat artificially divided into regions that include the external nasal valve, the internal nasal valve, the turbinated cavity, and the posterior nasal (choanae) aperture. The *nasal valves* comprise the major areas of resistance in the nasal cavity. The internal nasal valve is generally the "flow-limiting" segment of the nasal airway. According to Poiseuille's law, even small changes in the size of the internal nasal valve can have exponential effects on the airflow resistance. The size of the nasal airway is also governed by the physiologic alternating pattern of congestion and decongestion called the *nasal cycle.* This pattern of vascular engorgement of the capillaries involves the nasal lining in general and the vessels of the inferior turbinates specifically.

Anatomic Locations and Causes of Nasal Obstruction

The etiology of nasal airway obstruction is often multifactorial and may include both anatomic aspects and physiologic effects of the nasal and sinus mucosa.

Internal Nasal Valve

The *internal nasal valve* is typically the site of maximum resistance and frequently the cause of subjective complaints about obstructive nasal breathing. Obstruction that worsens during inspiration (i.e., dynamic obstruction) is usually caused by a weakening of the cartilaginous vault (i.e., the collapse of the ULCs and the LLCs) that is unable to withstand the inspiratory pressures. Static obstruction of the internal nasal valve occurs as a result of encroachment by the boundary structures of the valve. This is often the result of enlargement or hypertrophy of the inferior turbinates; deflection (i.e., thickening) of the nasal septum; medially located lateral nasal walls (i.e., maxillary constriction); an elevated nasal floor (i.e., long face growth pattern); or thickened and scarred nasal mucosa (i.e., as a result of allergies). During rhinoplasty, internal nasal valve collapse is prevented by avoiding the resection of the ULCs or the overresection of the LLCs. When either of these conditions is the cause, secondary reconstruction via the placement of spreader grafts is generally helpful.

External Nasal Valve

Common causes of static narrowing of the *external nasal valve* include alar malpositioning or scarring of the skin or nasal vestibule, caudal septal deflections, and nasal tip ptosis (see Fig. 38-4).[77] These may be seen after overzealous cleft lip nasal procedures. Dynamic collapse of the external nasal valve may be the result of weakened or deficient LLCs and nasal ala. During rhinoplasty, external nasal valve collapse is generally prevented by avoiding overaggressive resection of the LLCs and by preserving the soft-tissue support of the mobile alar walls. Secondary reconstruction to correct this deformity requires cartilage support grafts that are applied to the LLCs.

Posterior Nasal (Choanae) Apertures

Obstruction of the *posterior nasal apertures* may result from the skeletal structures that compose the choanae (i.e., the vomer and the palatine bones) or from the overlying soft tissues (i.e., polyps, adenoids, and turbinates).[210] Choanal atresia may also be associated with congenital anomalies such as CHARGE syndrome, Treacher Collins syndrome, and Apert syndrome.

Middle Turbinate Concha Bullosa

It is known that the majority of airflow through the nose enters the middle meatus, which is directly beneath the middle turbinate. A pneumatized *middle turbinate* (i.e., concha bullosa) is a common anatomic variation that occurs in approximately 25% of the population. If the concha bullosa is extremely large and associated with septal deviations, it may contribute to nasal obstruction.

Physiologic Causes of Nasal Obstruction

Both *benign and malignant neoplasms* may occur anywhere in the sinonasal tissues and should always be ruled out. *Inflammation* of the nasal mucosa is a common multifactorial process that results in edema and congestion of the nasal soft tissues. For example, *nasal polyposis* is thought to be triggered by a combination of factors (e.g., inflammation, asthma, allergy). If they are large enough, polyps may obstruct the nasal airway and the sinus ostium and result in blockages and sinus infections. *Allergies* are a common cause of sinoatrial inflammatory disease leading to turbinate hypertrophy, which further exacerbates ongoing complaints of nasal obstruction. *Hormonal changes* associated with pregnancy, menopause, and hypothyroidism are also known to have effects on the nasal mucosa and vasculature, with resulting obstructive nasal breathing. In an attempt to improve the symptoms of nasal obstruction, the overuse of prescription and over-the-counter *medications* (e.g., drugs from the imidazoline class, sympathomimetic amines) can also cause significant problems. The "rebound nasal congestion" phenomenon is well known and typically occurs with chronic use.

Evaluation of the Nasal Airway

Among the pertinent findings that require clarification from the patient are a history of nasal obstruction, sinusitis, or inflammatory sinonasal disease and the presence of a limited sense of smell or taste. A history of environmental or seasonal allergies, nasal surgery, or trauma should be correlated with physical findings.

With regard to the nasal airway, a complete external and internal nasal examination should be undertaken. Direct

and speculum examination of the anterior septum, the head of the inferior turbinates, and the external nasal valves should proceed. Nasoendoscopy allows for a more thorough examination of the nasal airway and should be undertaken when indicated to fully visualize the septum, the turbinates, the meatus, the nasal mucosa, the nasal valves, the posterior aperture, and other nasal structures. Decongestants may also be used to further assess the airway. For cases in which radiologic studies are needed, a coronal sinus computed tomography scan is useful.

The functional aspects of the nose that a rhinoplasty surgeon may typically alter include the nasal valve areas and the turbinated cavity. When completing a septoplasty procedure with the removal of posterior bony septal deflections, it is important to avoid injury to the cribriform plate, because cerebrospinal fluid rhinorrhea would result. As previously stated, when performing a septoplasty that includes the removal of deflected portions of quadrangular cartilage, it is important to maintain adequate caudal and dorsal struts for support of the nasal dorsum and tip.

The *internal nasal valve* is defined by both the valve angle (i.e., the relationship of the ULCs to the septum), which is typically 10 to 15 degrees, and the valve circumference. Respiratory obstruction can occur when the valve area is decreased by septal deviation, mucosal disease (i.e., engorgement of the inferior turbinates), scarring, and traumatic, neoplastic, congenital, or surgical deformities (e.g., narrow pyriform rim width, elevated nasal floor).

An example of effective reconstruction occurs when the internal nasal valves are collapsed after the surgical overresection of the ULCs, and *spreader grafts* (placed between the nasal septum and the ULC) are used to widen the internal valve angles. This will decrease nasal airway resistance and improve respiration.

Nasal airway resistance is greatly affected by the inferior turbinates, which periodically swell and decrease the internal valve area. Inferior turbinate hypertrophy may be physiologic or pathologic. For the majority of the population, a *normal "nasal cycle"* of the congestion and decongestion of the turbinates and the nasal mucosa is ongoing, with reciprocal changes on the two sides. The *total nasal airway resistance* in the healthy nose is remarkably constant, with changes occurring every 2 to 4 hours in the turbinates and the mucosal lining. When the inferior turbinates are markedly enlarged and when the process is not reversible with the use of vasoconstrictors and anti-inflammatory agents, then surgical reduction of the turbinate hypertrophy (often in combination with septoplasty) is the treatment of choice and will generally relieve the symptoms. Doing so will often open the internal nasal valve and the whole turbinated cavity. A variety of surgical techniques are used to accomplish the goal of inferior turbinate reduction (e.g., partial excision, electrocautery, submucosal resection, radiofrequency ablation, microdebridement).[157,173] The overaggressive resection of the inferior turbinates has, on occasion, resulted in rhinitis sicca or "dry nose."

Surgical Approach to Open the Nasal Airway

The clarification of any anatomic structures of the *internal nasal valve* that are causing blockage should be identified. This may include the following: 1) the septum 2) the anterior head of the inferior turbinates 3) the bony nasal floor 4) the lateral nasal walls (i.e., the tight inlet) 5) the ULCs; and 6) the nasal mucosal lining (i.e., the synechiae).

The identification of any anatomic components that interfere with the *external nasal valve* is also clarified and the areas surgically corrected, if feasible. This may require reconstruction of the LLCs, via elevation of the nasal tip or through the release of scar contracture of the nasal skin or the vestibular mucosa.

The opening of the *posterior nasal (choanae) aperture* may require the following: 1) the reduction of the adenoid pad; 2) the recontouring of the posterior floor of the nose and the lateral nasal walls; 3) the resection of the vomer and the perpendicular plate of the ethmoid; or 4) the horizontal (sagittal) advancement of the maxilla (i.e., Le Fort I osteotomy).

The partial removal (by direct excision, submucosal resection, or cauterization) of *hypertrophied middle turbinates* can, at times, significantly improve a patient's nasal airflow. If the middle turbinate is pneumatized (concha bullosa) and a cause of nasal obstruction found, it should be reduced by whatever means necessary.

Outcome Assessment of Surgery to Improve Nasal Breathing

Attempts to objectively measure alterations in nasal function after medical or surgical interventions that are carried out for the purpose of improving nasal breathing have proven to be difficult.[31,113-115,118,128,152,171,185,187,189,190,195,215,222,223,226,243] Through acoustic rhinometry and rhinomanometry, attempts at objective postoperative assessments of the nasal airway have been carried out. Consistent findings with the use of these measurement techniques are mixed at best. A spectrum of studies by different investigators has demonstrated conflicting results with similar research designs. Studies by Lindemann and colleagues confirm that nasophysiologic functions (e.g., the heating and humidifying of inspired air) were improved after successful septoplasty and appropriate inferior turbinate reductions.[126] This positive effect is believed to be derived from increased volumes and the direction of physiologic airflow to key places within the nasal passage, which increases mucosal contact with the nasal airstream. The improved flow dynamics may also improve the filtration of particulate matter more effectively.

In addition to objective instrumentation measures of nasal breathing, researchers have sought a standardized assessment of results from the patient's perspective. These

efforts have taken the form of symptom-based questionnaires. The most rigorously developed disease-specific measure for nasal obstruction was created by the *Nasal Obstruction Symptom Evaluation* (NOSE) study investigators.[233,234] The NOSE Scale generates an integral patient-specific score out of a possible 100 points and thus facilitates quantitative comparisons within subjects at different time points or among groups of subjects who are undergoing different treatments. *The NOSE Scale is now considered the reference standard for the assessment of alterations in nasal breathing.* Considering the extent of nasal obstructive treatment carried out in the United States alone, which is estimated to cost $5 billion per year, emphasis on standardization and measurable results seems to be indicated (see Chapter 10).

Initial Rhinoplasty Consultation

During the initial consultation, it is important for the patient to confirm any functional nasal difficulties and also to explain his or her facial aesthetic concerns. The individual may want a nose that is narrower (i.e., dorsal width reduction), less irregular (i.e., dorsal hump removal) and with a more attractive nasal tip (i.e., improved definition and projection). A frequently stated objective—or at least a personal desire that is expressed when an in-depth history is taken—is to have the ability to breathe better.

Aesthetic concerns often relate to an enlarged *osseocartilagenous vault* (e.g., dorsal hump, increased mid-dorsal width) or if a previous rhinoplasty was carried an over reduced dorsum and a narrow width. The *lobule and tip* may be drooped and bulbous, with a lack of definition, or they may be overreduced, pinched, and turned up as a result of a previous surgery. The *nasal base* may be overly wide or constricted, primarily as a reflection of the underlying skeletal or cartilaginous structures.

Difficulty with breathing through the nose is often chronic, with a longstanding mouth-breathing habit. If this is the case, the facial morphology may be that of a long face growth pattern (i.e., vertical maxillary excess typically with an anterior open-bite Class II malocclusion; see Chapter 21). The *obstructive nasal breathing* is often made worse in the presence of chronic allergies or with ambient changes in humidity. Examination of the *internal nose* may reveal septal deviations or perforations, external valve stenosis, internal nasal valve obstructions, posterior nasal aperture stenosis, turbinate enlargement, or an irritated nasal mucosal lining. Consideration should also be given to the *adenoids and tonsils,* which may be enlarged and obstructive. The *internal nasal valves,* the *turbinated cavities,* the *external nasal valves,* and the *posterior nasal aperture* may be obstructed by any one of a number of anatomic structures (e.g., turbinates, septum, ULC, LLC, nasal skeletal walls or floor, soft tissues).

During the initial consultation, consideration is given to the following: 1) the patient's stated objectives 2) any patient-specific anatomic limitations 3) the surgeon's concepts of the patient's facial proportions (i.e., the presence of a dentofacial deformity or isolated microgenia) and 4) the patient's nasal aesthetic unit (i.e., whether to reduce, augment, or sculpt one or more of the key regions of the nose).

It is also essential for the surgeon to understand the patient's *psychological reasons* for requesting surgery on the nose and then to assess that patient's emotional maturity and stability. Constantian has outlined specific red flags for the surgeon to be concerned about, including the patient who is seeking surgery for specific external gain (e.g., an individual who expects that nasal changes will improve his or her career); the narcissistic male; and the perfectionist.[41] He also warns against operating on an individual whom "you just don't like" (i.e., with whom you are not able to effectively communicate). Picavet and colleagues documented a high prevalence of body dysmorphic disorder symptoms among patients who are seeking rhinoplasty (see Chapter 7).[176] Individuals who request revision rhinoplasty and those with a psychiatric history are particularly at risk for ongoing dissatisfaction.

When the surgeon is satisfied that the patient has a problem or concern that can be physically and visually improved and that the patient is realistic with regard to his or her expectations and without notable psychopathology, further details of the proposed surgery can be outlined and frankly discussed.

Definitive Rhinoplasty Planning

A review of the patient's history, physical findings, facial photographs, and, if indicated, sinus computed tomography scan or other facial radiographs (e.g., lateral cephalometric, Panorex) is generally followed by a second consultation visit to finalize the operative plan. The surgical objectives are clarified after 1) hearing the patient's requests 2) analyzing the overall facial and specific nasal aesthetics and functional aspects 3) considering patient-specific anatomic limitations 4) discussing all options and 5) considering the surgeon's ideal treatment plan.

Basic questions for the surgeon to consider include the following:

- Are there any medical or psychosocial contraindications to elective nasal surgery?
- What are the functional nasal findings? Do they correlate with the patient's symptoms?
- Are there associated maxillomandibular disproportions that affect the individual's facial aesthetics?
- What aspects of the patient's nose would the surgeon like to change?

- Given the quality of the patient's overlying nasal skin and the underlying skeletal and cartilaginous structures, what are the reasonable surgical options?
- Do the patient's requests match the surgeon's thoughts when taking into account any biologic limitations of the tissues?
- Does the surgeon think that he or she can interact effectively with the patient should a complication or suboptimal result occur?

By the end of the second consultation visit, a definitive operative plan should be clear in the surgeon's mind and accurately conveyed to the patient. The patient and the surgeon should be comfortable with any compromises that are agreed to and with the expected outcomes and the potential risks. If a comfort level is not reached, it is best not to proceed.

Most primary rhinoplasties require a combination of the reduction and augmentation of various aspects of the nose. This will often include the following: 1) the reduction of the bony and cartilaginous dorsum 2) the reduction of the cephalic portions of the LLCs (lateral crura) 3) middle crural suturing 4) cartilage (caudal strut) graft augmentation and 5) nasal osteotomies with in-fracturing (to narrow the width, to accomplish the closure of an open roof, or to straighten a crooked dorsum). When indicated, the removal of any septal deviations (i.e., cartilage and bone) and the reduction of the inferior turbinates will simultaneously diminish airway resistance and improve nasal breathing.

Open versus Closed Approach to the Nose

In the hands of a limited number of experienced nasal surgeons, the closed (endonasal) approach to gain exposure of the nose allows for the predictable management of the patient's needs.[91,198,202,217-221] In this author's clinical practice, the open (columella-splitting and bilateral marginal incisions) approach provides the preferred direct exposure of the nasal structures in most patients. After elevation of the nasal soft-tissue envelope via an open approach, direct inspection of the osseocartilaginous framework and tip should confirm the preoperative clinical diagnosis. This direct exposure facilitates technical maneuvers such as the following: 1) bony and cartilaginous reduction 2) excision and suturing of the LLCs 3) the placement and stabilization of grafts and 4) septal modification. By understanding normal nasal physiology and what the osseocartilaginous framework and nasal tip should look like and then seeing the anatomy under direct vision, the intended results are achieved more often than not.

As pointed out by many authors, the open approach has advantages that include the following[3,4,33,50,72-76,84,91,101,112]:

1. Securing a cartilage (strut) graft to the caudal septum to help control or maintain the tip position
2. Suturing the middle crura to each other and then over the top of the secured caudal (strut) graft to improve tip projection and shape
3. Controlling the columellar–lobular angle by altering the axis of the caudal strut graft
4. Suturing additional nasal tip grafts in place over the top of the LLCs
5. Accurately placing and securing spreader grafts to correct nasal valve collapse, to straighten the nose, and to correct saddle deformities
6. Placing and suturing cartilage grafts to reinforce, change the shape of, or replace missing segments of the lateral crura
7. Placing and securing onlay grafts (over the bony or cartilaginous vault) to reconstruct or augment the dorsum of the nose
8. Visualizing and then reducing the bony and cartilaginous nasal dorsum
9. Visualizing and then reducing or modifying the radix, including the placing and securing of grafts

An often-stated drawback of the open approach relates to tip swelling. The amount and duration of tip swelling after open rhinoplasty is generally greater than that seen with the closed approach. Therefore, it is reasonable to consider a closed rhinoplasty for those patients who may need only nasal osteotomies, dorsal hump reduction, or minimal tip alterations.

Complications Associated with Rhinoplasty

Fortunately, in the hands of an experienced nasal surgeon, the vast majority of well-informed patients undergo an uneventful operative and postoperative course and are pleased with their initial and long-term function and their aesthetic results. However, as with any surgical procedure, perioperative problems may occur (e.g., infection, bleeding, airway compromise) in addition to problems that are specific to rhinoplasty (e.g., septal perforation, persistent nasal obstruction, suboptimal cosmetic results).* These potential problems must be considered and openly discussed in advance to limit patient dissatisfaction.

Infection

Infection occurs in approximately 1% of patients who are undergoing elective rhinoplasty.[35,37,54,83,109,129,166] The routine use of prophylactic antibiotics that are started just before

*References 10, 13, 41, 52, 102, 118, 130, 133, 148, 168, 188, 238

surgery and continued postoperatively (at least until all internal nasal packs have been removed) is recommended. If infection occurs, appropriate drainage and culturing of the fluid is carried out. The antibiotic regiment is altered, as indicated.

Bleeding

Intraoperatively, bleeding is generally more of an annoyance than a problem. Minor postoperative nosebleeds are managed with elevation of the head, compression, packing, and time. When postoperative bleeding persists, a determination is made with regard to whether the hemorrhage is anterior or posterior, and appropriate packing of the nose is carried out. Cauterization of the bleeding points and rechecking of the hemoglobin level, the clotting studies, and the platelet function may be indicated. Ongoing hemorrhage that requires blood transfusion or the proximal ligation of branches of the external carotid artery is exceedingly rare. Bleeding is more likely to follow turbinate reduction than any other septorhinoplasty maneuver.

Airway Obstruction

The assessment of nasal breathing and of the entire upper airway should be carried out and the findings discussed with the patient and the family before rhinoplasty occurs.[16,18,20,43,94,111,150,151,194,214] The importance of doing this has been confirmed by Thomson[240] and Hellings,[104] who independently reported the presence of persistent nasal airway obstruction as a frequent complaint that leads to need for revision rhinoplasty. The nasal airway may also be compromised as a result of rhinoplasty. Synechiae may form between the septum, the lateral nasal wall, or the turbinates and require release in the office or, occasionally, in the operating room. Residual septum deflections may require removal. Further turbinate reduction may also be advantageous. The clinician should not ignore the nasal airway if a favorable result and a satisfied patient are desired.

Septal Perforation

Full-thickness holes (perforations) in the septum after a septoplasty are thought to occur in less than 5% of patients. The occurrence of septal perforations is dependent on the quality of the patient's nasal mucosal lining, the surgical technique, and the complexity of the deformity. Long-term problems associated with perforations range from annoyance (e.g., crusting, occasional bleeding, whistling as a result of turbulence on inspiration) to external deformities (e.g., saddle-nose depression as a result of septal collapse) with nasal obstruction; see the discussion later in this chapter. The repair of septal perforations is extremely difficult. Currently, a reliable routine method for the correction of septal perforations has yet to be realized.

Dry Nose Syndrome

Atrophic rhinitis is uncommon, but it may be seen after turbinate reduction.[59,149] There may be gradual and progressive atrophy of the nasal mucosa with a lack of moistening secretions that leads to crusting that accumulates. The crusts harbor bacteria; when this is associated with poor aeration and drainage, an unpleasant odor (ozena) may result.

Burn Injuries

The occurrence of operating room fires and airway burns is rare. Nevertheless, there is a risk of ignition in the operating room with any application of electrocautery or lasers. This risk is increased in the setting of nasal-cannula or face-tent supplemental oxygen. It can also be a problem in the intubated patient in whom there is an "air leak." Facial burns, intraoral and intra-airway burns, and even patient demise have all been reported. Although burn injuries in the operating room are rare, they represent approximately 20% of all malpractice claims for cases performed under monitored anesthesia care, and 95% of these cases involve surgery of the head and neck.[196]

Patient Dissatisfaction

Studies indicate that, on average, 15% of patients who have undergone cosmetic rhinoplasty procedure will express at least some dissatisfaction with the result.* In general, rhinoplasty patients differ from facial aging patients with regard to their psychological complexity. Most individuals who are seeking rhinoplasty have always been dissatisfied with some aspect of their facial appearance, which they attribute to nasal dysmorphology. Alternatively (at least in theory), the adult facial aging patient is seeking rejuvenation to restore a previous "satisfactory" appearance. The rhinoplasty patient is more likely motivated by lifelong body-image undercurrents that mold his or her perception of the nasal appearance. This will influence his or her expectations for surgery in a way that different from those of the facial aging patient.

Adamson and colleagues report that patients who request primary rhinoplasty commonly cite their rationale as including a "dorsal hump" (50%); a "too large" nose (44%); a bulbous tip (41%); and an "obstructed nasal airway" (33%).[32] Because half of the patients seeking primary rhinoplasty cited a "dorsal hump" as the chief concern, the achievement of an aesthetically pleasing nasal profile is essential. This is contingent on a thorough understanding of the underlying nasal anatomy and a complete facial analysis, which includes the assessment of the true dorsal hump as well as looking for the presence of a deep radix or an underprojected tip. Care should also be taken to establish a pleasing contour and transition between the dorsum and the tip (i.e., the supratip break) and to prevent iatrogenic deformities (i.e., supratip "Polly beak"

*References 41, 52, 67, 68, 102, 116, 176, 191, 245

deformity). Other surgical causes of patient dissatisfaction include cartilage graft warping, resorption, and palpability. Another frequent reason for a primary rhinoplasty consult is a nose that is "too large" (44%). The achievement of a good nasal profile will therefore frequently depend not only on the anatomy of various nasal parts but also on the interplay of the other facial parts (i.e., the maxilla, the mandible, and the chin region). The discerning clinician must separate out these aspects (i.e., dentofacial disharmony versus nasal disharmony) if patient satisfaction and a favorable outcome are to be achieved (see Chapters 19 through 23 and Fig. 38-2).

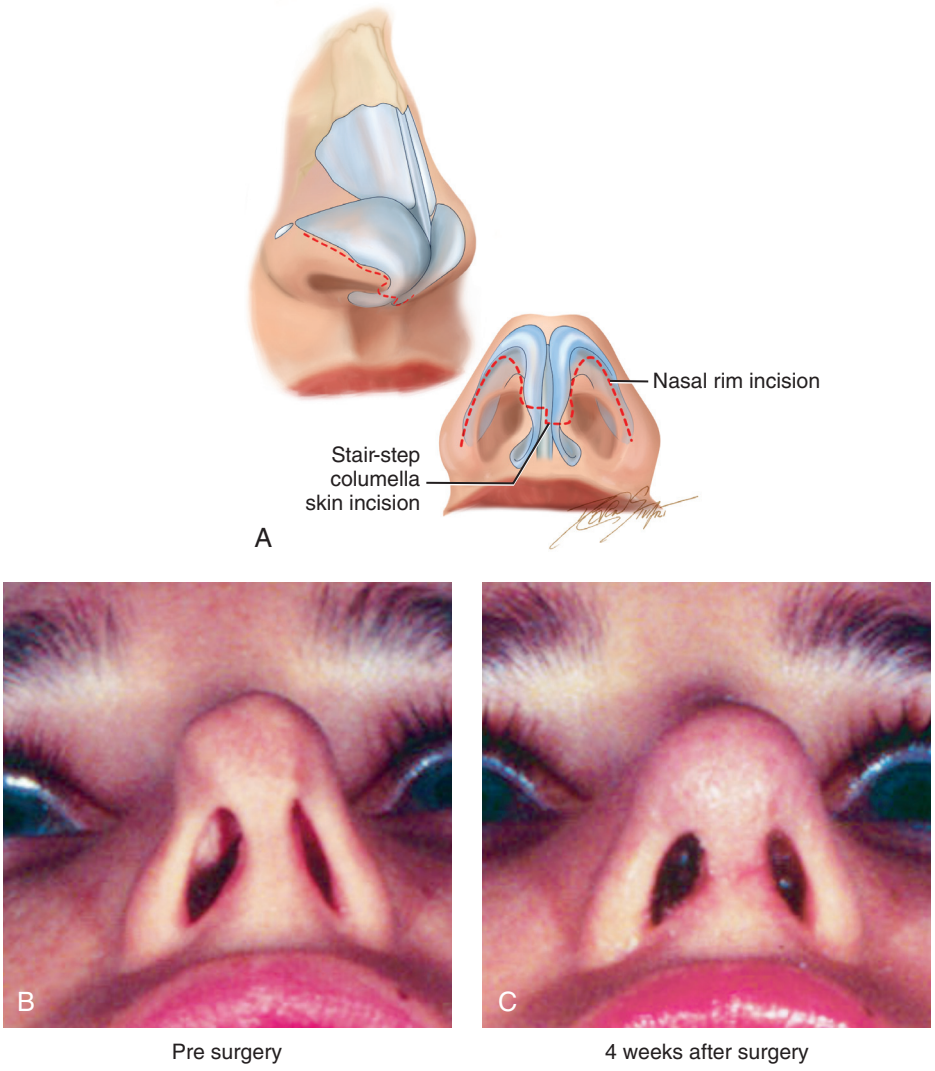
Rohrich and colleagues pointed out the importance of understanding the psyche of the male rhinoplasty patient.[200] These patients are more likely to present with nonspecific complaints, to be more demanding of the end result, and to be less attentive during the consultation visit. The clinician must painstakingly set clear and realistic expectations of the operation to achieve patient satisfaction. These authors recommend allowing 6 to 12 months of healing before agreeing to further nasal modifications. In most reported series, only 50% of patients who undergo revision rhinoplasty will move into the satisfied category.[41]

Primary Septorhinoplasty: Step-by-Step Approach (Figs. 38-5 through 38-9)

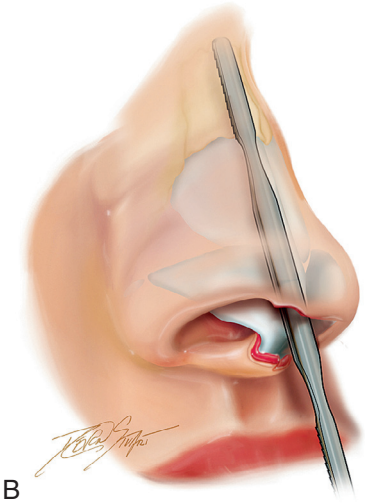
Preparation and Draping

- Complete the orotracheal (RAE) intubation, and tape the tube to the skin of the chin.
- Apply the ophthalmic ointment and place the corneal shields for eye protection.
- If the patient has long hair, tie it in a ponytail.

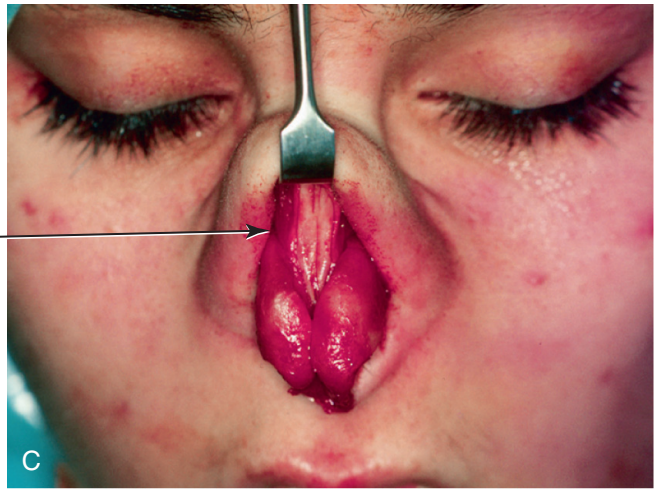
Text continued on p. 1632

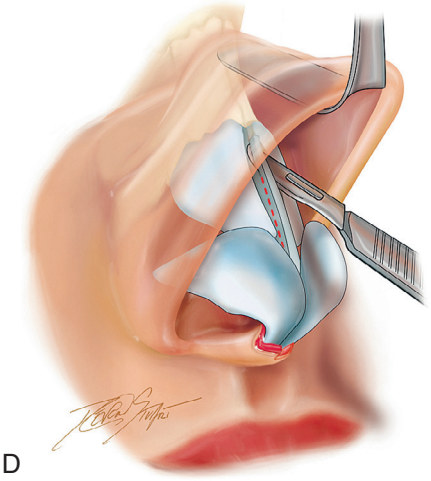


• **Figure 38-5** Incisions that are used for an open technique rhinoplasty are demonstrated. **A,** Stair-step columella (skin) and bilateral (intranasal) rim incisions are illustrated in two views. **B,** Worm's-eye views of the nose before and **C,** 4 weeks after an open-technique secondary rhinoplasty. Four weeks after surgery, the skin incision is immature (i.e., red and raised), and the soft tissues remain swollen.

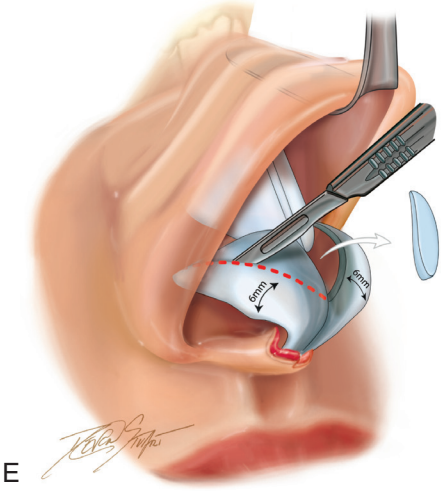


Removal of dorsal bony "hump" under direct vision

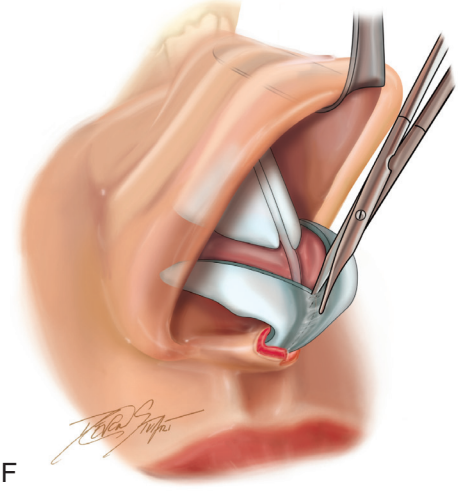




Removal of dorsal cartilage "hump" under direct vision



Knife used to reduce cephalic excess of lower lateral cartilages



Scissors used to separate lower lateral cartilages and expose caudal aspect of septum

• **Figure 38-6 A,** Exposure of the deep structures, including the lower lateral cartilages (LLCs), as viewed through an open approach after the elevation of the soft-tissue envelope of the nose. **B,** A rasp is used to reduce the bony dorsum of the nose. **C,** The upper lateral cartilages and the dorsal aspect of the quadrangular cartilage are also directly visualized through the open approach. **D,** Dorsal bone reduction (as described in **B**) is followed by the sharp knife excision of the cartilaginous dorsal hump. The illustration shows the Aufricht retractor in place, with a knife (no. 15 blade) used to excise excess dorsal septal cartilage. **E,** Measurement of the LLCs is carried out with a caliper. In general, a 6-mm caudal rim of LLC is maintained. The cephalic excess is incised with a knife (no. 15 blade) and then removed with a Stevens scissors. **F,** An illustration that shows the scissors dissection to separate the LLCs and to expose the caudal aspect of the quadrangular cartilage.

Caudal strut graft sutured in place, lower lateral cartilages are then sutured together and over the top of the graft

• **Figure 38-6, cont'd J,** An illustration showing an incision through the quadrangular cartilage to initiate submucous resection. It is important to maintain an uninjured and adequate dorsal and caudal strut of cartilage to structurally support the nose. *(1)* A knife (no. 15 blade) is used to initiate the incision in the septal cartilage. *(2)* A swivel knife will then be introduced to complete the actual submucous resection of the septal cartilage. The cartilage excision corresponds with needed graft for augmentation or with the removal of septum that is interfering with breathing. **K,** An illustration of the extent of maximum septum (bone and cartilage) that may be removed to improve the airway. This includes much of the quadrangular cartilage and bone (i.e., vomer and perpendicular plate of ethmoid). The removed quadrangular cartilage available graft is shown. The yellow-colored aspect of the removed quadrangular cartilage indicates the planned caudal strut graft. **L,** An illustration of the crafted cartilage (strut) graft sutured to the caudal aspect of the remaining septal cartilage. The LLCs are then sutured together and over the top of the strut graft. This type of suture has been called a *medial crural fixation suture*. The sutures are placed to fix one medial crus to the other, thereby unifying the medial crura beneath the domes and then above the strut graft. This combination of techniques allows for the preferred nasal tip projection, shape, and orientation.

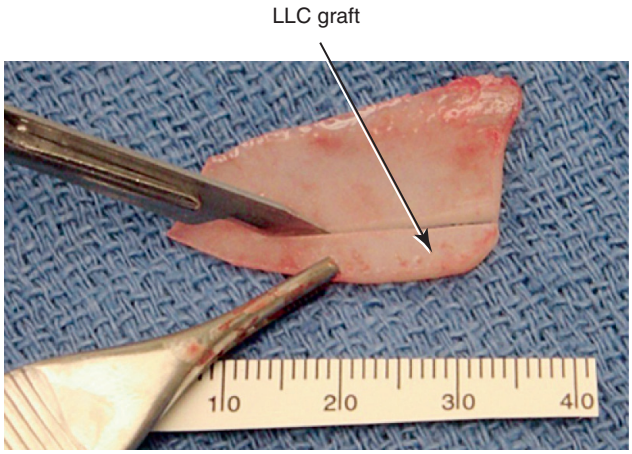
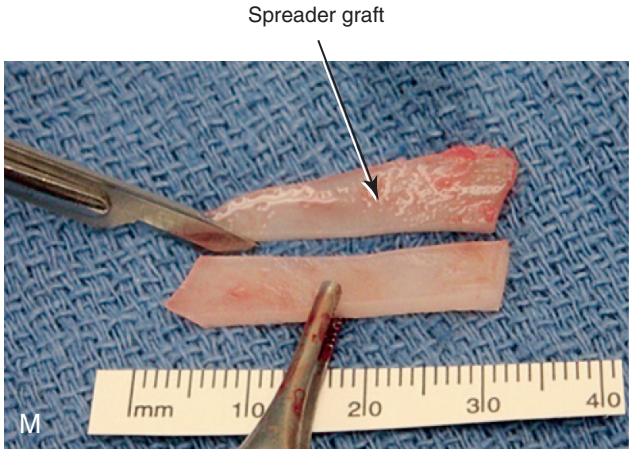
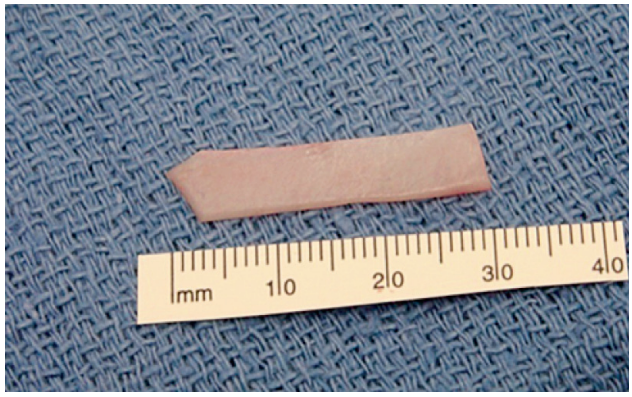
Removed septal cartilage



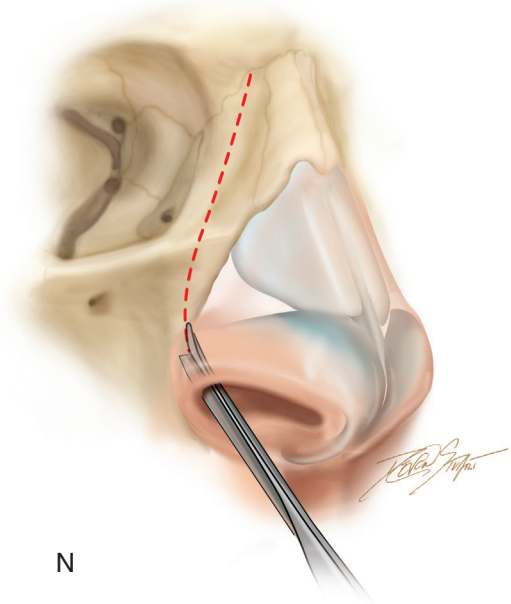
Inferior excision



Superior excision

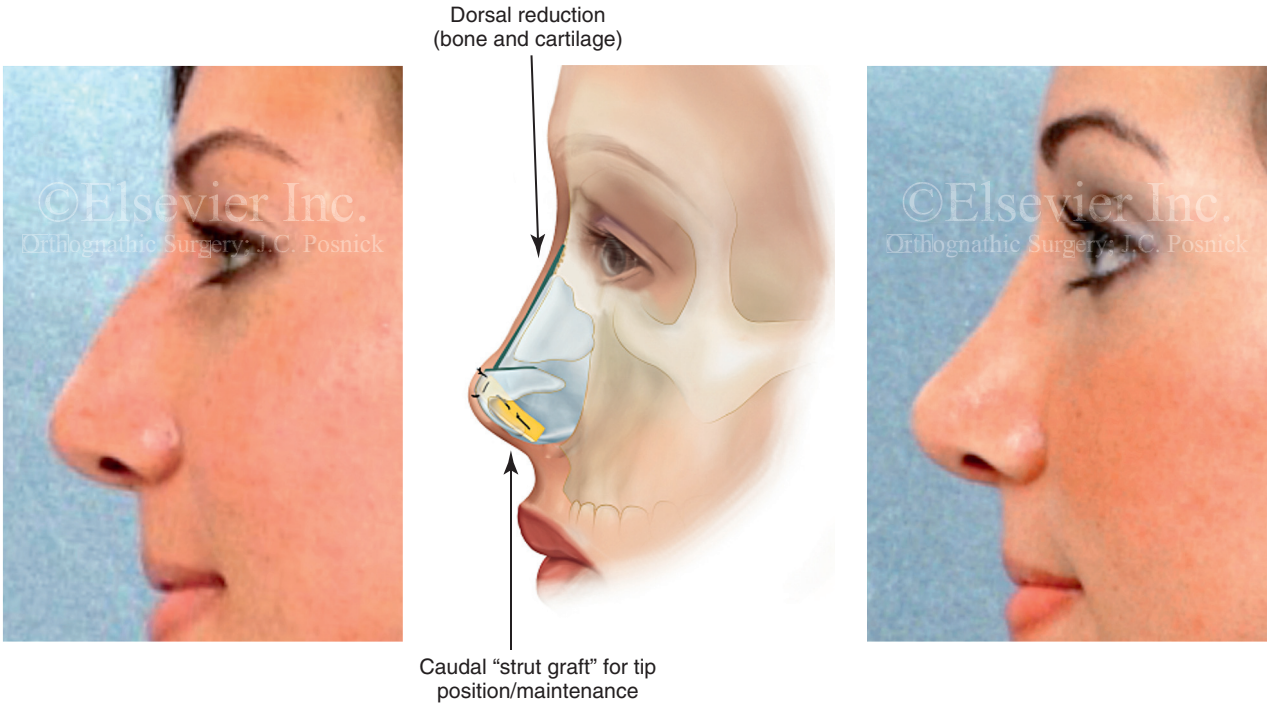


Caudal “strut” graft



Guarded ostetomy used to complete nasal
osteotomy through intranasal pyriform rim incision

• **Figure 38-6, cont’d M,** Intraoperative views of removed septal cartilage, which can be used as graft material to reconstruct the nose. The cartilage can be crafted as a caudal strut, spreader grafts, LLC augmentation grafts, or tip onlay grafts. **N,** Nasal osteotomies are completed by first identifying the piriform rim intranasally with a speculum; the speculum blades straddle the bony rim. An incision is completed through the nasal mucosa on the side of the anterior maxilla to expose the piriform rim. The speculum is removed, and a Joseph elevator is inserted. Subperiosteal tunneling in the location of the proposed osteotomy is carried out. A curved and guarded osteotome is introduced through the intranasal incision, and the osteotomy is completed. The osteotomy is performed through the pyriform rim (maxilla), lateral to the nasomaxillary suture, and then up toward the nasofrontal suture on each side. The nasal bones are then in-fractured with finger pressure and positioned as desired.



• **Figure 38-7** Profile views of the nose highlighting a young woman before and after rhinoplasty with the use of the techniques described in the legend for Figs. 38-5 and 38-6. An illustration highlights the combination of dorsal reduction (bone and cartilage) and nasal tip alteration (i.e., caudal strut cartilage grafting and lower lateral cartilage reshaping) typically carried out to achieve the objectives.

• **Figure 38-8** A woman in her 20s underwent a septorhinoplasty procedure as described previously. She is shown at 1 week and 4 weeks after surgery. At her 1-week visit, the custom-formed Aquaplast splint and skin sutures were removed.

- Use Betadine solution (do not use soap, alcohol, Hibiclens and so on) to prepare the scalp, forehead, external ears, face, and neck.
- Complete draping and leave the forehead, external ears, face, and neck exposed in the operative field.

Surgical Marking

- Locate and use a surgical pen to mark the columella (stair-step) incision and the bilateral rim (marginal) intranasal incisions before prepping and draping.

Local Anesthesia

- Inject Xylocaine (1% with 1:100,000 epinephrine) within the soft-tissue envelope of nose as usual for rhinoplasty.
- Inject Xylocaine (1% with 1:100,000 epinephrine) on each side of the septum, deep to the mucosa and superficial to the cartilage.
- Place either cocaine-soaked (5 mL of 4% solution) or Afrin-soaked pledgets in each nostril cavity.

Skin Incisions and Flap Elevation

- Incise the columella skin and the intranasal rims with a knife (#15 blade).
- Elevate the nasal soft-tissue envelope with Stevens scissors as required for an open rhinoplasty procedure.
- Elevate the overlying cutaneous soft-tissue envelope up the columella, superficial to the LLC and ULC, subperiosteal over the nasal bones (with a Joseph elevator) to the radix, and lateral toward the maxillary process on each side.
- Clean the subcutaneous tissue off of the superficial surface of each LLC with the use of Stevens scissors.

Dorsal Reduction

- If a dorsal bony hump requires reduction, it is conservatively completed with coarse and fine diamond rasps.
- If a dorsal cartilaginous hump requires reduction, it is conservatively incised with a knife (no. 15 blade) under direct visualization.

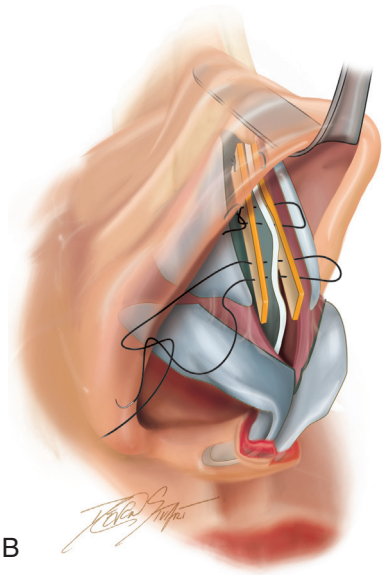
Lower Lateral Cartilage Modification

- The LLCs are separated from their midline soft-tissue connections with the use of Stevens scissors. Dissection continues down to the caudal aspect of the septum.
- The LLCs are marked with a caliper and trimmed of cephalic excess. In general, at least 6 mm of caudal LLC is retained. The redundant cephalic portions are incised with a knife (no. 15 blade) and removed with Stevens scissors.

Exposure and Resection of Portions of Septum

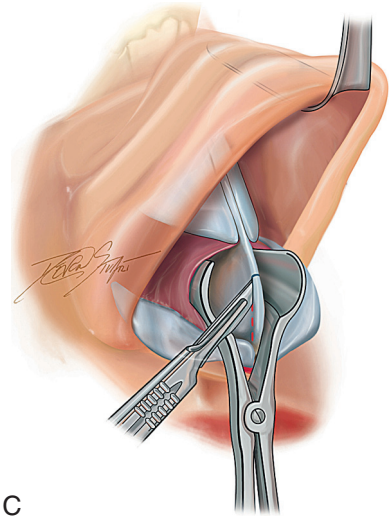
- Identify the anterior aspect of the caudal septal cartilage. (Dissection to the septum has already been completed with Stevens scissors.) A knife (no. 15 blade) is used to remove the final layer of perichondrium from the caudal

• **Figure 38-9** Three frequent maneuvers that are used to alter the cartilaginous vault and nasal tip are highlighted. For each of these three techniques, an illustration and a patient example are shown. Other rhinoplasty maneuvers were also simultaneously carried out on each patient. **A,** A frequent surgical technique to improve the position of the nasal tip is the harvesting of the septal cartilage, which is then crafted as a caudal strut. The caudal strut is sutured to the native septum and vectored to improve tip position and for maintenance. The lower lateral cartilages are then sutured together and over the top of the graft.

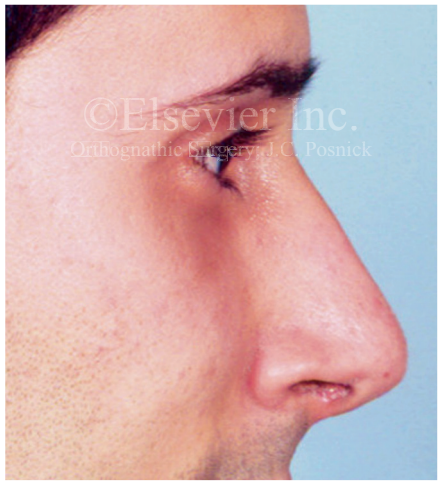


B

Spreader grafts from septal cartilage are sutured in place to straighten a "crooked" cartilagenous vault



C



• **Figure 38-9, cont'd B,** Spreader grafts may be crafted from harvested septal cartilage. They are placed on each side of the dorsal aspect of the quadrangular cartilage and sutured together. Spreader grafts can be helpful to open the internal nasal valves and to straighten a crooked cartilaginous vault. **C,** Altering the caudal aspect of the quadrangular cartilage to achieve improved aesthetics in the columella region is often a necessary aspect of rhinoplasty. When there is excessive "columella show" seen in profile, the excision of the redundant caudal septal cartilage will be helpful. A patient example and an illustration are shown. In other circumstances, when there is inadequate "columella show" (i.e., retracted columella), augmenting the caudal aspect of the septum with a cartilage graft will be a useful approach (see Chapter 29).

edge of the septal cartilage before dissection. Next, use a sharp Cottle elevator to achieve submucosal exposure on each side of the septal cartilage. Extend the submucosal dissection inferiorly to the maxillary ridge and posterior to the vomer. Continue the subperiosteal dissection as required for the exposure and resection of the deviated bony septum (i.e., to the vomer and the perpendicular plate of the ethmoid).

- If the caudal aspect of the quadrangular cartilage requires reduction (i.e., to limit columella show), it is sharply incised with a knife (no. 15 blade), and the redundant portion is removed under direct visualization.
- Submucosal resection of the cartilaginous septum is initiated with the use of a knife (no. 15 blade) to control the caudal and dorsal aspects of the excision. The knife incisions are located to maintain approximately 10 mm of caudal and 10 mm of dorsal septal cartilage support for the nose. This is followed by the insertion of a swivel knife.
- The swivel knife is used to excise the deviated, buckled, or thickened septal cartilage (i.e., submucosal resection) and to harvest a graft, as indicated.
- A rongeur (either a double action or a Takahashi) is used to remove any buckled, deviated, or thickened portions

of the vomer and the perpendicular plate of the ethmoid that are obstructing nasal airflow (i.e., submucosal resection).

Reduction of Inferior Turbinates

- If the inferior turbinates are hypertrophic and require partial reduction, this is accomplished by one of several methods, including scissors resection of the inferior aspect of each turbinate; out-fracture; submucosal (intramural) removal; or submucosal cauterization.

Completion of Nasal Osteotomies

- A short nasal speculum is inserted intranasally with one forceps blade placed on either side of the pyriform rim.
- An incision is made with a knife with a no. 15 blade piercing the nasal mucosa down to the bone along the piriform rim of the maxilla.
- A Joseph elevator is used to dissect (tunnel) subperiosteally up toward the nasofrontal suture where the osteotomy is to be completed.
- A curved, guarded osteotome is inserted through the intranasal incision that saddles the pyriform rim. A mallet is used to drive the osteotome and to complete the osteotomy.
- The same procedure is completed on the other side.
- The nasal bones are in-fractured, disimpacted for adequate mobility, and then reoriented in accordance with aesthetic preference.

Reconstruction of Nasal Tip

- Craft the required grafts (e.g., caudal strut, LLC grafts, spreader grafts, tip graft) with a knife (no. 15 blade) from the full piece of harvested septal cartilage
- If a caudal strut graft is required, it is crafted and then positioned near (abutted to) the caudal aspect of septal cartilage to achieve improved nasal tip position. It is held in the preferred location with pinching forceps or a needle and then sutured to the side of the septal cartilage with the use of interrupted stitches (5-0 Vicryl).
- The LLCs, having been trimmed of cephalic excess, are sutured together and then over the caudal strut graft to form the most superficial aspect of the nasal tip (5-0 Vicryl). This type of suture has been called a *medial crural fixation suture*; it is used to fix one medial crus to the other, thereby unifying the medial crura beneath the domes and then above the caudal strut graft.
- The soft-tissue envelope is redraped and the nose is inspected to confirm adequate dorsal reduction, proper tip projection and position, satisfactory columella show, and straightness of the nose. Further refinements are made, if needed. (They usually are!)

Wound Closure

- After the completion of the septorhinoplasty procedure, closure of the wound is accomplished.
- To approximate the columella skin (stair-step incision), a single buried dermal suture is placed (5-0 Vicryl).
- The columella skin closure is with interrupted suture ties (6-0 nylon).
- The intranasal rim incisions are closed with interrupted ties (5-0 chromic).

Placement of Dressing

- Routine dressing is placed as they are after a septorhinoplasty procedure.
- Flexible splints (Reuter) are generally placed (one on each side of the septum) and secured together with single suture tie (3-0 nylon).
- Antibiotic ointment (Bactroban) is generally injected into each nostril cavity.
- When nasal osteotomies are carried out, nasal packing is helpful to maintain the preferred nasal bone position. Packing (folded Telfa) is generally inserted equally into each nostril cavity.
- Tape is placed over the dorsum of the nose (Steri-Strips) as it is after rhinoplasty.
- A custom splint (Aquaplast) is molded over the dorsum of the nose as it is after rhinoplasty.

Images of a series of individuals are shown to demonstrate the spectrum of presentations and the typical results achieved with the use of the techniques just described (Figs. 38-10 through 38-18).

Cleft Nasal Deformities

Background

Through the dissection of a stillborn fetus with unilateral cleft lip and palate (UCLP), McComb documented that tissue distortions and malpositions are primary factors in the cleft nasal deformity.[37,136] Byrd and colleagues also completed the dissection of a stillborn fetus with UCLP and confirmed hypoplasia of the LLC complex in addition to malpositions.[25] They also found an abnormal fixation of the lateral crus to the periosteum of the pyriform rim.

The primary (unrepaired) cleft nasal malformation in an individual with UCLP is characterized by features that include the following: 1) malposition and hypoplasia of the LLC with fibrous attachment of the lateral crus to the pyriform rim 2) interruption of the muscle ring (orbicularis oris) across the clefted nasal sill with abnormal muscle insertions at the alar base to the cheek and to the lip and 3) soft-tissue clefting through the nasal floor (Figs. 38-19 and 38-20). In the unilateral complete cleft lip nasal

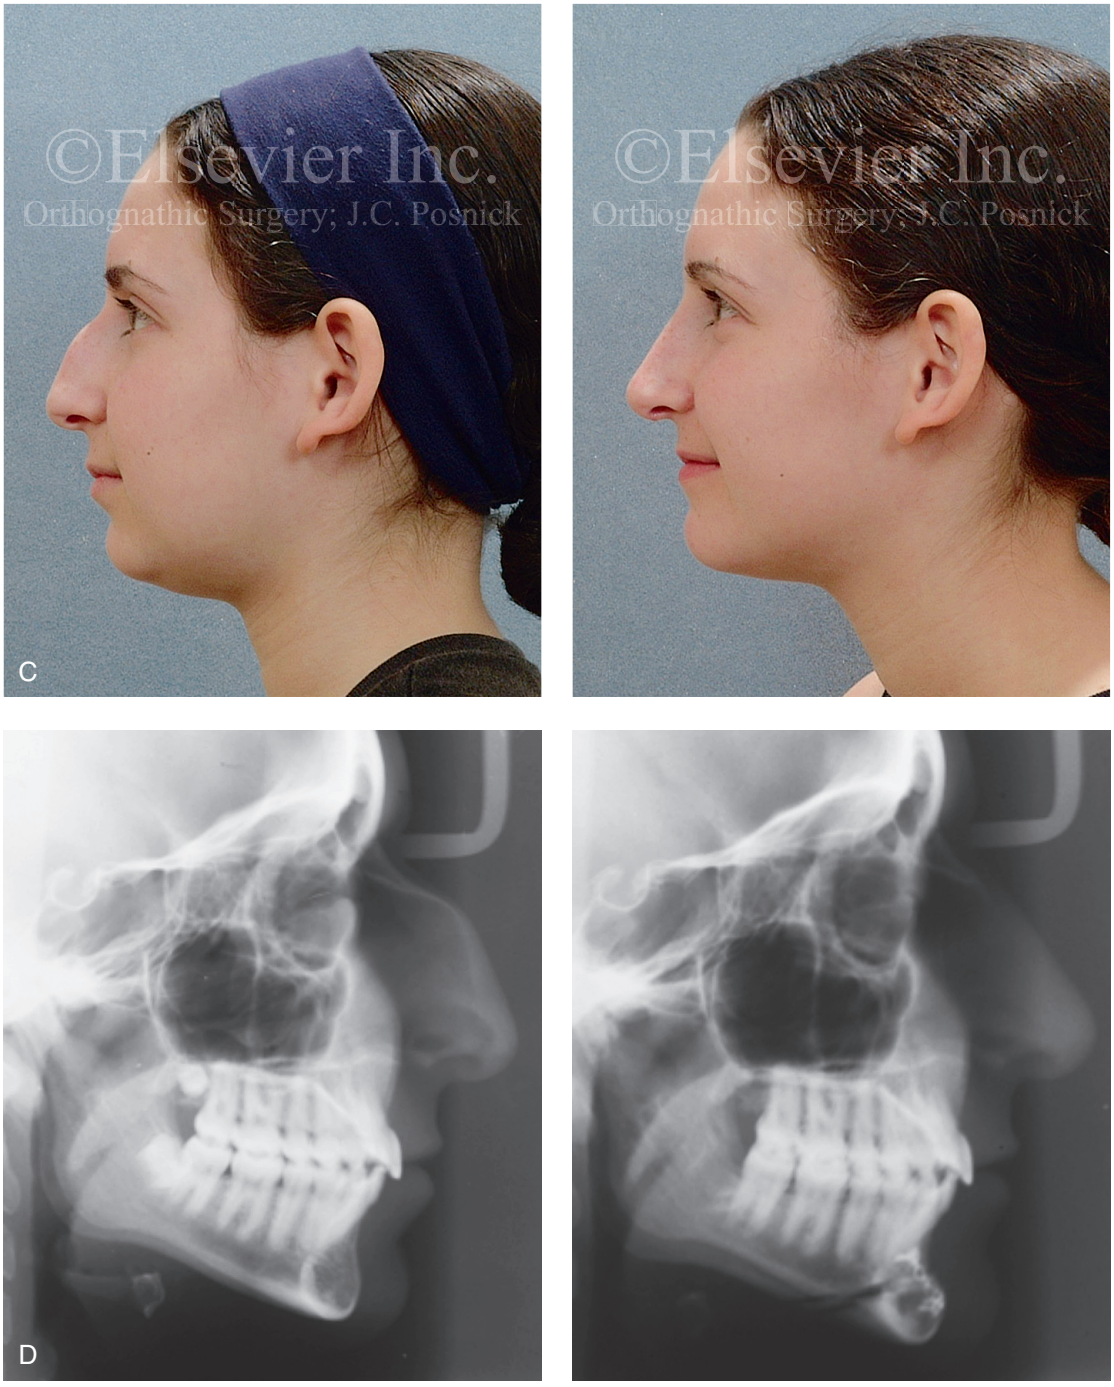
• **Figure 38-12** A teenage girl arrived with her parents and requested cosmetic rhinoplasty and the improvement of her nasal breathing. She underwent an open rhinoplasty that included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage); tip refinement (reshaping of the lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and inferior turbinate reduction. **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Profile views before and after reconstruction.

• **Figure 38-13** A teenage girl arrived with her parents and requested a "smaller and more attractive" nose. Rhinoplasty to reduce the dorsum and elevate the tip in combination with genioplasty to improve the profile was recommended. She underwent osseous genioplasty (vertical lengthening and horizontal advancement) and open rhinoplasty that included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage); tip refinement (reshaping of the lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and inferior turbinate reduction. **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction.



• **Figure 38-13, cont'd C,** Profile views before and after reconstruction. **D,** Lateral cephalometric radiographs before and after reconstruction. Note the interpositional bloc hydroxyapatite graft that was used to achieve successful chin lengthening.

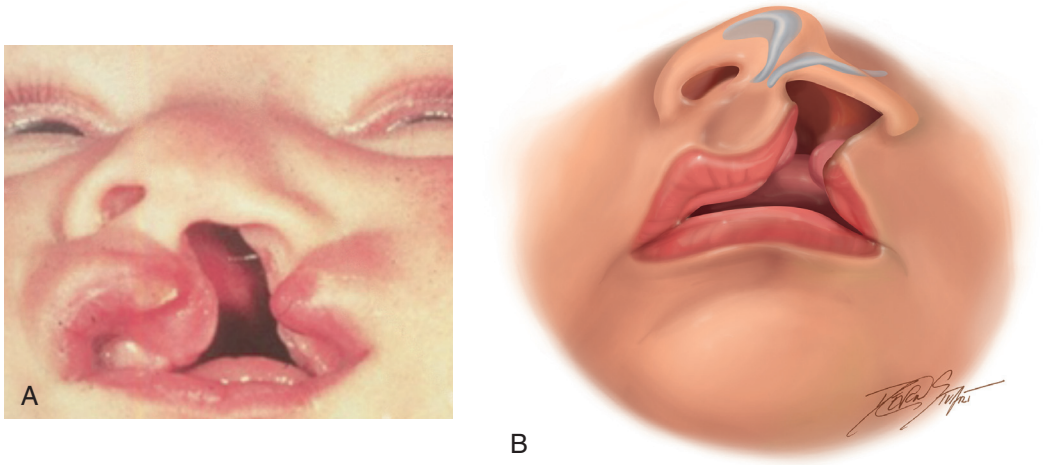
• **Figure 38-14** A teenage girl arrived with her parents and requested cosmetic rhinoplasty to narrow the mid dorsum, to remove the dorsal hump, and to improve tip projection. Her history also confirmed significant nasal obstruction. She underwent an open rhinoplasty that included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage); tip refinement (reshaping of the lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and inferior turbinate reduction. Note that the thick quality of the nasal skin limits the aesthetic result. **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Profile views before and after reconstruction.

• **Figure 38-15** A woman in her mid 20s requested cosmetic rhinoplasty and the improvement of her nasal breathing. She also has a mild long face growth pattern and prominent ears. She requested that surgery be limited to the nose. The nasal objectives included the removal of the dorsal hump, the narrowing of the mid dorsum, and the improved positioning of the tip. She underwent an open rhinoplasty that included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage); tip refinement (reshaping of the lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and inferior turbinate reduction. **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Profile views before and after reconstruction.

• **Figure 38-16** A woman in her early 50s requested cosmetic rhinoplasty and the improvement of her nasal breathing. She hoped for improved tip projection and the removal of the dorsal hump. She underwent an open rhinoplasty that included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage); tip refinement (reshaping of the lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and inferior turbinate reduction. **A,** Oblique facial views before and after reconstruction. **B,** Profile views before and after reconstruction.

• **Figure 38-17** A woman in her late 40s requested cosmetic rhinoplasty to improve tip projection and to reduce the dorsal hump. She also requested relief of the hooding of the upper eyelids. She underwent an open rhinoplasty that included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage); and tip refinement (reshaping of the lower lateral cartilages and septal cartilage caudal strut grafting). She also underwent upper blepharoplasty (removal of excess skin). **A,** Oblique facial views before and after reconstruction. **B,** Frontal views before and after reconstruction.

• **Figure 38-18** A 28-year-old man of Arabic descent had previously sustained a fracture of the nasal bones. As a result, he had difficulty breathing and was displeased with the aesthetics (i.e., dorsal hump, crooked nose, drooped nasal tip). He underwent an open rhinoplasty that included nasal osteotomies (in-fracture); dorsal reduction (bone and cartilage); nasal tip maneuvers (reshaping of the lower lateral cartilages and septal cartilage caudal strut grafting); spreader grafts (septal cartilage); septoplasty; and inferior turbinate reduction. **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Profile views before and after reconstruction.



• **Figure 38-19** Demonstration of a typical unilateral cleft lip nasal malformation. **A,** Worm's-eye view of a newborn with unilateral cleft lip and palate (UCLP). **B,** Illustration showing the typical dysmorphology of the maxillary base, the caudal septum, and the nasal tip in a newborn with unrepaired unilateral cleft lip and palate.

malformation, asymmetric anatomic distortions (e.g., displacement of the septum to the non-cleft side) also require special consideration.[225,252] In the bilateral complete cleft lip nasal malformation, there is minimal asymmetry but shortening of the height of the columella is to be expected (see Figs. 38-31 and 38-32).

Nasal Deformities in the Newborn with Unilateral Cleft Lip and Palate (see Figure. 38-19)

- The perpendicular plate of the ethmoid deviates toward the cleft side.
- The posterior aspect of the quadrangular cartilage deviates toward the cleft side.
- The anterior aspect of the quadrangular cartilage deviates toward the non-cleft side.
- The anterior nasal spine deviates toward the non-cleft side.
- The bony pyramid of the nose (nasal bones) deviates toward the non-cleft side.
- The nasal bones are asymmetric and generally flattened on the cleft side.
- The ULCs are asymmetric and have a disturbed junction with the LLCs on the cleft side.
- There is a tendency toward the bifidity of the nasal tip.
- There is a buckling of the lateral crus of the LLC on the cleft side.
- There is a downward position of the medial crus of the LLC on the cleft side.
- There is a deviation of the nasal tip to the cleft side.
- There is a deviation at the nasal base to the non-cleft side.
- There is a lateral, downward, and posterior displacement of the alar base on the cleft side.

Basic Nasal Reconstructive Maneuvers during the Primary Unilateral Lip Repair (Figures. 38-20 and 38-21)

- Along the lateral aspect of the nose, the nasal soft tissues (including the inferior turbinate) are released from the piriform rim and the lateral nasal wall with the use of an elevator (Fig. 38-21, *A*).
- Next, the buckled and flattened lateral crus of the LLC is released from the overlying nasal soft tissues with the use of Stevens scissors (Fig. 38-21, *B*).
- The elevated lateral nasal flap (including the inferior turbinate) will be advanced medially, superiorly, and anteriorly to facilitate nasal sill and floor reconstruction (Fig. 38-20, *D*).
- Along the medial aspect of the nose, the nasal soft tissues (including the medial crus of the LLC) is released from the anterior nasal spine and septal cartilage with the use of an elevator and Stevens scissors (Fig. 38-21, *C*). The elevated medial nasal flap will be advanced laterally to facilitate nasal sill and floor reconstruction (Fig. 38-20, *D*).
- The release of the orbicularis oris muscle from its abnormal soft-tissue and bone attachments is accomplished with the use of Stevens scissors. Reconstruction of the orbicularis oris muscle with interrupted sutures achieves continuity across the lip (Fig. 38-20, *D*).
- Recurrent buckling of the lateral crus of the LLC early after surgery is limited by the placement of an intranasal stint (i.e., packing). Sutures through the nasal soft tissues and LLC may also be used to elevate and maintain the shape of the rim (Fig. 38-21, *D*).

Three typical patients with UCLP that have been treated with the techniques described are shown after primary repair (Figs. 38-22 through 38-24). Maneuvers that are

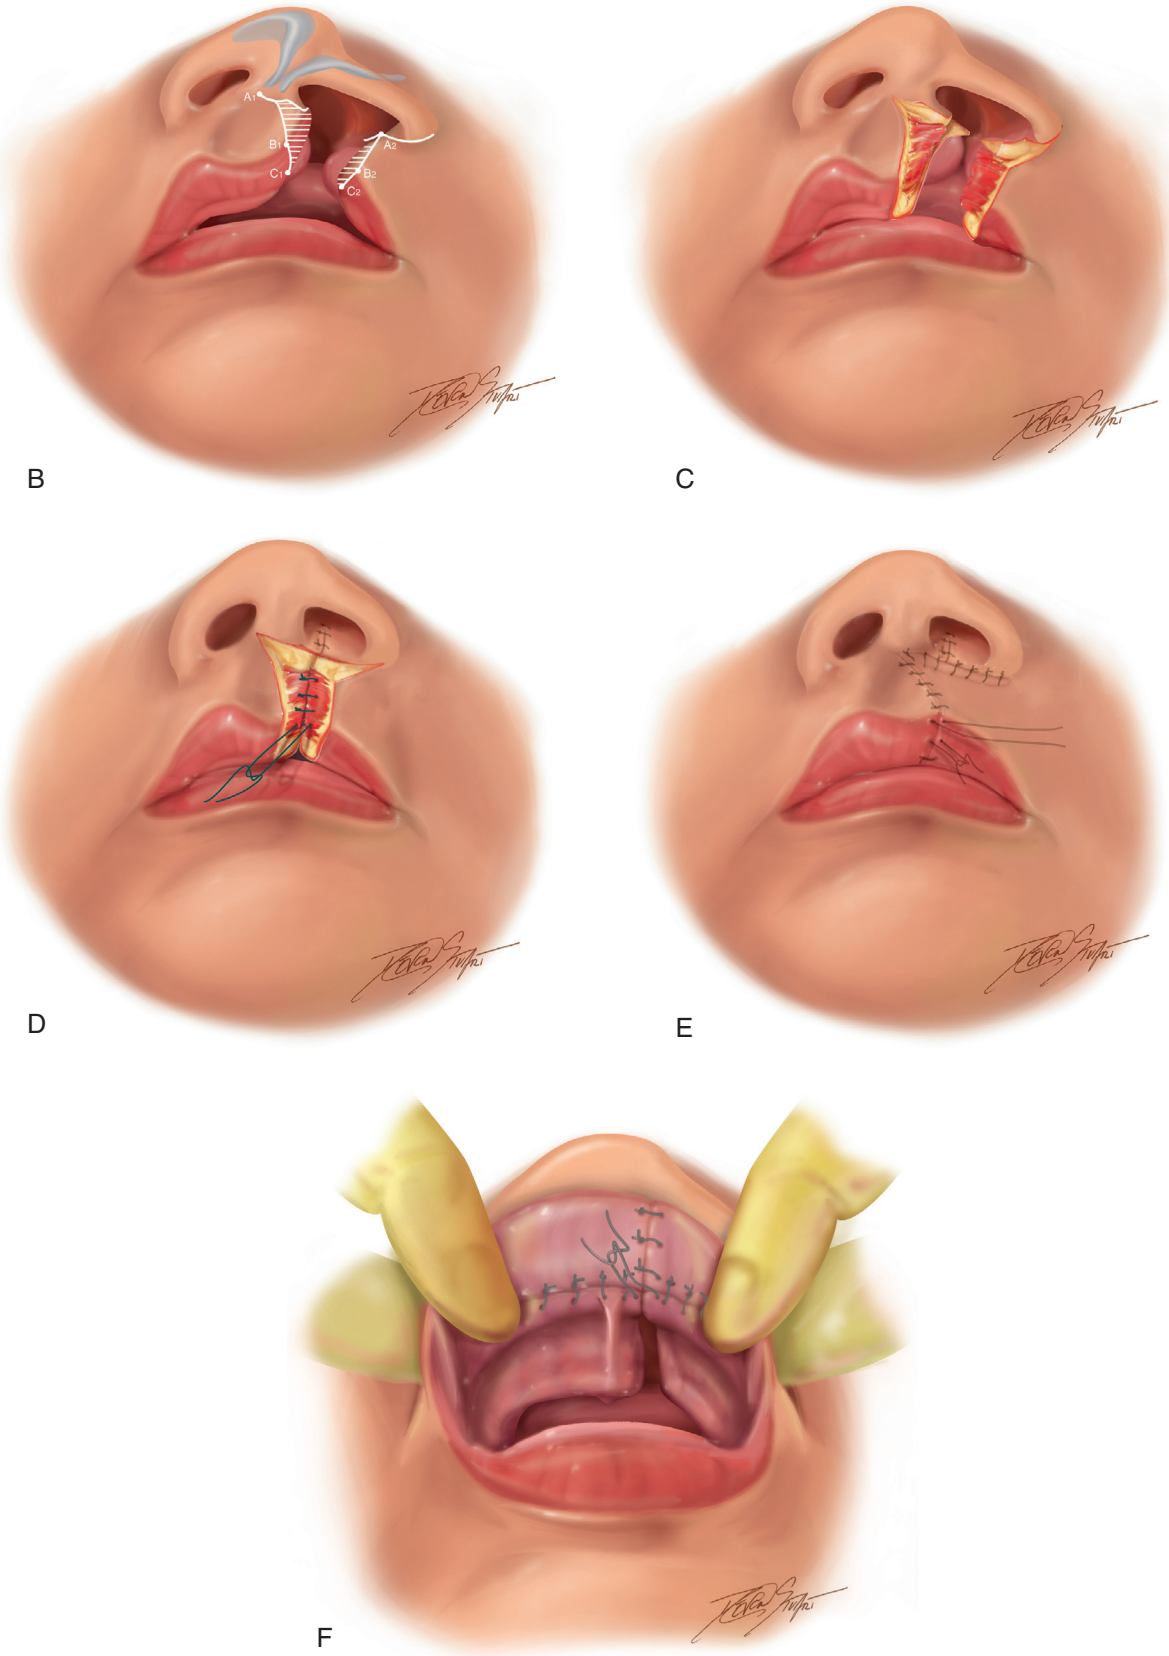
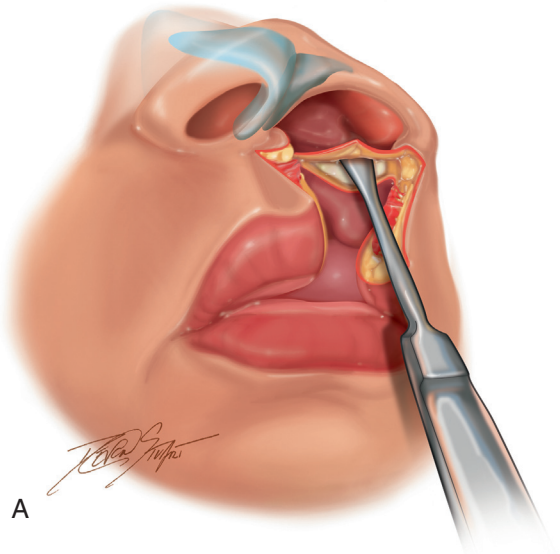
A

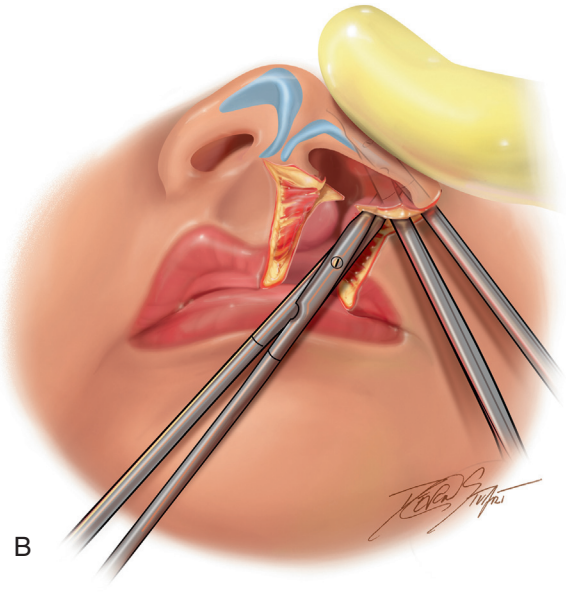
• **Figure 38-20 A,** Illustration of the typical facial malformations and distortions in a newborn with unilateral cleft lip and palate.



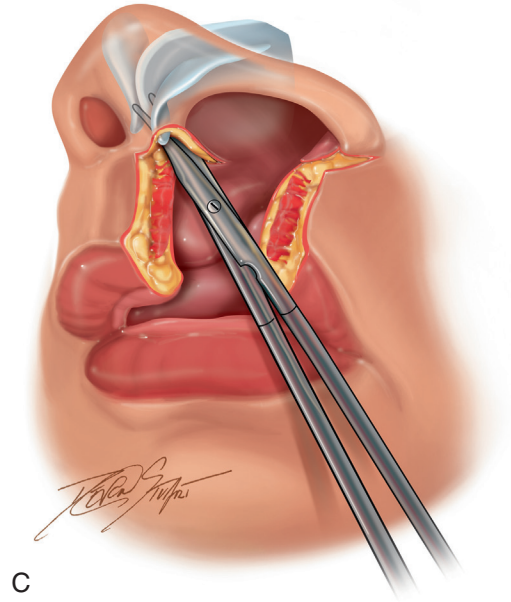
• **Figure 38-20, cont'd B,** Illustration of the modified "Millard" rotation and advanced cutaneous flaps used by this author for primary lip reconstruction and the basic nasal maneuvers that are simultaneously carried out. Incision locations for the lip rotation flap (greater segment) and the lip advancement flap (lesser segment) are outlined. Incision locations for the medial and lateral nasal flaps are also shown. **C,** The incisions are made and the flaps are elevated. Redundant tissue is excised, and the dissection of each lip flap from the underlying bone and cartilage is completed. The three tissue layers (i.e., the skin, the orbicularis oris muscle, and the underlying oral mucosa) are further separated from each other. **D,** The orbicularis oris muscle, having been released from its abnormal bony and soft-tissue attachments, is sutured across the midline to the base of the columella. Before this is done, the medial and lateral nasal flaps will have been elevated (see Fig. 38-21). After the orbicularis oris muscle has been repaired with sutures, the anterior aspect of the nasal floor is reconstructed with the use of the medial and lateral nasal flaps. **E,** The cutaneous lip rotation and advancement flaps are then approximated without tension over the repaired muscle for wound closure. The corner of the advancement lip flap fills the void at the base of the columella and is secured with suture. Precise approximation of anatomic landmarks with fine sutures is then undertaken to align the vermilion–mucosa junction and the vermilion–cutaneous junction. The philtral column and the nasal sill are also sutured. **F,** The underlying oral mucosa is reconstructed and sutured to establish a functional vestibule. Note: Alveolar clefting and oronasal fistula remains.



Lateral nasal flap elevation prior to lip repair



Dissection of LLC from overlying skin prior to lip repair



Nasal stent in place (UCLP)

• **Figure 38-21** Illustrations of unilateral cleft nasal maneuvers that are carried out as part of the primary lip and nasal reconstruction. **A,** Along the lateral aspect of the nose, the nasal soft tissues (including the inferior turbinate) are released from the pyriform rim and the lateral nasal wall with the use of an elevator that is inserted through the open lip. **B,** Next, the buckled and flattened lateral crus of the lower lateral cartilage is released from the overlying nasal soft tissues with the use of Stevens scissors inserted through the open lip. The elevated lateral nasal flap (including the inferior turbinate) will be advanced medially, superiorly, and anteriorly to facilitate nasal floor reconstruction (see Fig. 38-20, *D*). **C,** Along the medial aspect of the nose, the nasal soft tissues (including the medial crus of the lower lateral cartilage) are released from the anterior nasal spine and septal cartilage with the use of an elevator and Stevens scissors. The elevated medial nasal flap will be advanced laterally to facilitate nasal floor reconstruction (see Fig. 38-20, *D*). **D,** Recurrent buckling of the lateral crus early after surgery is limited with the use of an intranasal stint (packing). Sutures through the nasal soft tissues are also placed to pexy the lower lateral cartilage.

• **Figure 38-22** A newborn with a complete unilateral cleft lip and palate on the left side is shown before and 4 years after primary repair. He did not undergo any taping, molding, pinning, or adhesion procedures before the lip repair. When he was 3 months old, he underwent primary cleft lip repair in combination with primary nasal reconstruction as described (see Figures 38-20 and 38-21). When he was 12 months old, he underwent cleft palate repair with the use of the Bardach two-flap technique. He is shown **A,** as a newborn; **B,** at 18 months of age (6 months after palate repair); and **C,** at 3 years of age.

• **Figure 38-23** A child was born with incomplete clefting of the left primary palate; the secondary palate is also clefted. There is marked nasal deformity and clefting through the alveolus. She did not undergo any taping, molding, pinning, or adhesion procedures before the lip repair. At the time of primary cleft lip repair, she underwent nasal reconstructive maneuvers as described previously in the legends for Figs. 38-20 and 38-21. This was followed by palate repair when she was 12 months old with the Bardach two-flap technique. She is shown **A,** as a newborn; **B,** at 3 months of age (1 week after primary repair); **C,** at 1 year of age just before palate repair; **D,** at 4 years of age; and **E,** at 8 years of age after alveolar bone grafting.

• **Figure 38-24** A newborn with a complete UCLP on the right side is shown before and 7 years after primary repair. She did not undergo any taping, molding, pinning, or adhesion procedures before the lip repair. At 3 months of age, she underwent primary cleft lip repair in combination with primary cleft nasal reconstruction as described previously in the legends for Figs. 38-20 and 38-21. When she was 12 months old, she underwent cleft palate repair with the Bardach two-flap technique. She is shown **A,** as a newborn; **B,** at 3 months of age (2 weeks after primary lip and nose repair); and **C,** at 7 years of age just before alveolar bone grafting.

performed by some clinicians to alter the nasomaxillary anatomy before primary reconstruction (i.e., taping, nasoalveolar molding, Latham pinning, lip adhesion) were not carried out in any of these patients.[2,78,117,229,244] Interestingly, the American Cleft Palate–Craniofacial Association parameters of care document that addresses primary cleft lip and nasal repair includes only the following statements[172]:

- Surgical repair of the cleft lip is usually initiated within the first 12 months of life and may be performed as early as is considered safe for the infant.
- Presurgical maxillary orthopedics to improve the position of the maxillary alveolar segments before surgical closure of the lip may be indicated for some infants.
- The nasal deformity is an integral part of the cleft lip [malformation]. Depending on the severity, primary nasoplasty may be performed at the time of primary lip repair.
- A preliminary lip adhesion is a procedure that may be used in selected patients before definitive lip repair.
- The goal of lip repair is to restore the normal functional and anatomic features.

Interestingly, a recent survey of North American cleft surgeons indicated that only 50% of clinicians carry out any form of primary nasal reconstruction.[12,236] Ongoing evidence-based clinical research will be required to further clarify standards of care that address primary cleft lip and nasal repair.

Residual Nasal Deformities in the Adolescent or Adult with Repaired Unilateral Cleft Lip and Palate

Residual nasal deformities in the adolescent or adult with repaired UCLP are characterized first by uncorrected features of the primary malformation that may be compounded by previous surgical maneuvers and ongoing unfavorable nasomaxillary growth. Lesser degrees of the malformation will be seen in the adult, depending on the success of primary nasal reconstructive maneuvers.[31,33,60,127,147,160,177,178,232,253,254] The most favorable definitive rhinoplasty results in the patient with UCLP are achieved when issues with the underlying maxillary skeleton (including irregularities and defects of the floor of the nose, the piriform rims, and the anterior nasal spine) are first corrected (Figs. 38-25 through 38-30). Even if mixed-dentition bone grafting of the cleft skeletal defects is successful, nasal rim and floor recontouring and orthognathic procedures will be required in the majority of patients before definitive rhinoplasty is performed (see Chapter 32). The correction of the presenting UCLP nasal deformities in the adolescent or adult requires consideration of the following:

- The maxillary position in relation to the mandible below and the facial skeleton above
- The shape and symmetry of the piriform rims, the nasal floor, and the anterior nasal spine
- The morphology of the osseocartilaginous nasal vault
- The symmetry and projection of the nasal lobule and tip
- The quality of the nasal soft-tissue envelope
- The quality of the internal nasal lining
- The deformities of the septum and the turbinates

Alar Rims and Nasal Tip

The ipsilateral alar rim may lie caudal, lateral, and posterior as compared with the contralateral side. A hypoplastic malposed LLC may be superimposed on a residual underlying maxillary deformity. An incompletely repaired orbicularis oris muscle may also be a factor. Nasal tip projection is often inadequate, with asymmetry and foreshortening toward the cleft side.

Orthognathic Surgery; J.C. Posnick

• **Figure 38-25** A teenage girl was born with UCLP of the right side. Despite her having recently undergone a rhinoplasty by another surgeon, residual nasal deformities remained. She was referred by her orthodontist to this surgeon with concern about the residual cleft dental issues and jaw alignment. The patient wished to discuss the appearance of protruding ears and residual cleft nasal deformities. The bothersome nasal features included a dorsal hump, a drooped and asymmetric nasal tip, and difficulty breathing. She refused any further maxillary skeletal procedures. She agreed to an open rhinoplasty that included nasal osteotomies (in-fracture and straightening); dorsal reduction (bone and cartilage); nasal tip maneuvers (modification of the lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and inferior turbinate reduction. She also underwent simultaneous external otoplasty that included conchal reduction (elliptical excisions) and deepening of the scaphal folds (Mustarde stitches). **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Profile views before and after reconstruction.

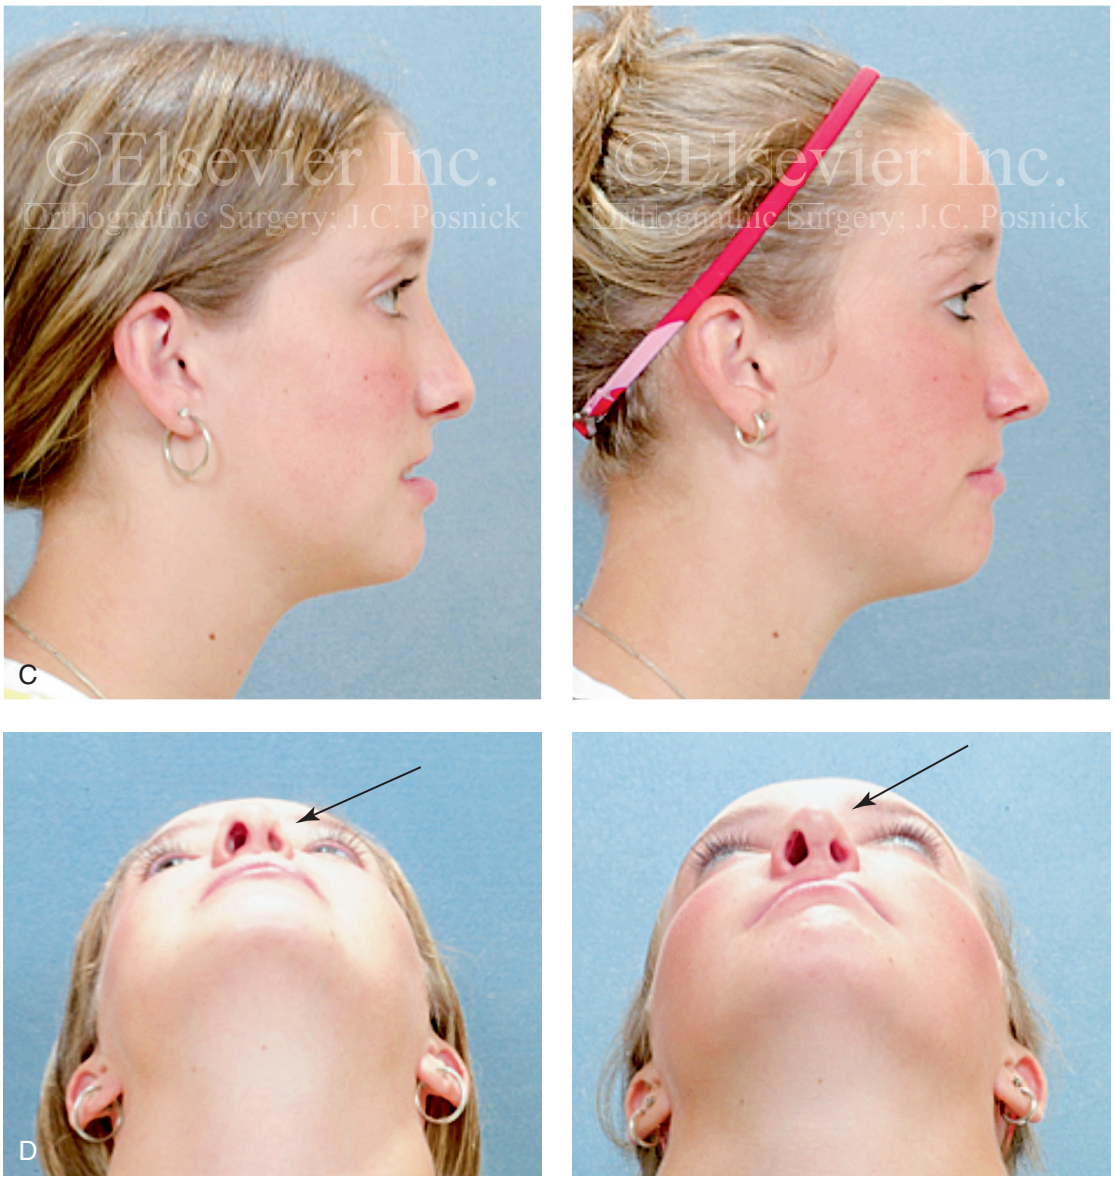
• **Figure 38-26** A teenage girl who was born with UCLP of the left side underwent primary lip and palate repair at another institution. She was referred to this surgeon and underwent successful bone grafting during the mixed dentition followed by the orthodontic closure of the cleft–dental gap. Growth of the maxilla was satisfactory, with good occlusion achieved with the use of orthodontic mechanics. She was displeased with the residual cleft nasal deformities, which included an asymmetric flat tip of the nose, a cicatrized left nasal opening, and a lifelong history of difficulty breathing through the nose. She underwent an open rhinoplasty that included nasal osteotomies (in-fracture and straightening); minimal dorsal reduction (bone and cartilage); nasal tip maneuvers (modification of the lower lateral cartilages and septal cartilage caudal strut grafting); septoplasty; and inferior turbinate reduction. **A,** Frontal views with smile before and after reconstruction. **B,** Oblique facial views before and after reconstruction.



• **Figure 38-26, cont'd C,** Profile views before and after reconstruction. **D,** Worm's-eye views before and after reconstruction. Note the irreversibly cicatrized left external nasal valve as a result of overresection at the time of primary lip repair.

Skeletal Framework of the Nose

The nasal bones are frequently wide and asymmetric. The dorsum itself may be high, low, or normal, with much individual variation. The mid cartilaginous vault may be curved, with collapse toward the side of the cleft.

Maxillary Base

The maxilla may be sagittally retrusive but more so on the cleft side, which results in the ipsilateral pyriform aperture being located caudal, lateral, and posterior. Previous bone grafting to the hard palate, the alveolus, and the floor of the nose may have been ineffective, with continued defects and asymmetry.

Nasal Airway

Asymmetric narrowing of the nasal cavity with obstruction to airflow is generally present. The septum may be displaced from the vomerine groove, and the cartilaginous portion may be thickened and buckled. The inferoanterior portion of the septum is typically displaced away from the cleft, whereas the superior cartilaginous septum curves into the cleft as it rises to the tip. The inferior turbinates, especially on the cleft side, are frequently hypertrophic; they consume much of the airway space with the collapse of the internal nasal valve. The bony septum may also be deviated. The floor of the nose just above the incisors will be asymmetric

• **Figure 38-29** A young man was born with complete UCLP. He was treated by other surgeons with procedures that included primary cleft lip repair; cleft lip revision; primary cleft palate repair; cleft palate revision; the placement of superiorly based pharyngeal flap; iliac grafting of the cleft defect; cleft rhinoplasty; and Le Fort I osteotomy with distraction osteogenesis (RED device). When he was 17 years old, he was then referred to this surgeon with residual cleft deformities that included the following:

- Nasopharyngeal stenosis with obstructive sleep apnea (apnea–hypopnea index: 11.4 events/hour, with desaturations to 89%)
- Persistent oronasal fistula
- Residual cleft jaw deformity with Class III open-bite malocclusion
- Chronic nasal obstruction with septal deviation and enlarged turbinates
- Residual cleft nasal deformity
- Cleft lip scar deformity with a lack of continuity of the orbicularis oris muscle

The patient agreed to a comprehensive orthodontic and surgical approach. His procedures included the following: redo Le Fort I osteotomy in two segments (+7 mm horizontal advancement , transverse widening, and oronasal fistula closure) with iliac grafting; bilateral sagittal split osteotomies of the mandible (horizontal advancement and clockwise rotation); oblique osteotomy of the chin (horizontal advancement and vertical shortening); redo septoplasty; redo inferior turbinate reduction; and recontouring of the nasal rims. One year later, the patient underwent cleft rhinoplasty, including rib cartilage (caudal) strut grafting; cleft lip scar revision, including repair of the orbicularis oris muscle; and the revision of the pharyngeal flap to relieve stenosis. A postoperative attended sleep study confirmed complete resolution of the obstructive sleep apnea. **A,** Frontal views in repose before and after reconstruction. **B,** Facial view with smile before and after reconstruction.

Continued

• **Figure 38-29, cont'd C,** Oblique facial views before and after reconstruction. **D,** Profile views before and after reconstruction. Note that the pharyngeal flap revision (release of stenosis) was important to resolve mucous trapping and to improve breathing.

• **Figure 38-30** A teenager was born with complete UCLP of the left side. He was treated by this surgeon with procedures that included cleft lip repair (3 months of age); cleft palate repair (12 months of age); superiorly based pharyngeal flap (5 years of age); and cleft bone grafting with fistula closure during the mixed dentition (8 years of age). He is congenitally missing the left maxillary lateral incisor and the first bicuspid. He underwent standard orthodontic treatment and had satisfactory growth of the jaws. Dental gaps remain for eventual implants and dental restorations. When he was 15 years old, he underwent nasal reconstruction that included septoplasty; inferior turbinate reduction; and rhinoplasty including rib cartilage (caudal) strut grafting. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

Continued

• **Figure 38-30, cont'd C,** Oblique facial views before and after reconstruction. **D,** Profile views before and after reconstruction.

and irregular, thereby further preventing the normal flow of air. The external valve may be scarred and cicatrized from previous surgery, which also further constricts nasal airflow.

Analysis of Residual Nasal Deformities in the Adolescent or Adult with Repaired Unilateral Cleft Lip and Palate

Key Points

- Is the nasal lining deficient or just distorted?
- Is the overlying nasal soft-tissue envelope deficient or just distorted?
- Are the nasal bones deformed and require reconstruction?
  - How is the dorsal height? How is the mid-dorsal width?
  - Is the bony vault crooked?
- Is the mid-cartilaginous vault crooked?
- Is the nasal tip projection adequate?
- Does the external nasal valve have scar cicatrization?
- What is the extent of the LLC deficiency? Will augmentation be required?
- Is the skeletal component of the nasal aperture deficient and asymmetric? If so, bone grafting, fistula closure, and/or recontouring will be required.
- Is the maxilla hypoplastic? If so, orthognathic surgery will be indicated.
- What are the current areas of nasal obstruction
  - External nasal valves?
  - Internal nasal valves?
  - Turbinated cavities?
  - Posterior (cavity) apertures?
  - Tight pharyngeal flap?
  - Tonsils and adenoids?

In most patients with repaired UCLP, an adequate overlying soft-tissue envelope and underlying internal nasal lining are present. Although the nasal bones are deformed, they are usually adequate to allow for reconstruction through a combination of osteotomies and dorsal reduction. The mid-cartilaginous vault may be crooked to the extent that spreader grafts are required. A cartilage caudal strut graft will be required for tip straightening and projection in virtually all cases. If the septal cartilage is available, it is usually adequate. If greater structural support is required, the use of rib cartilage is preferred. If the quality of the LLC is adequate, reconstruction simply by recontouring and suture-pexy is carried out. If not, then augmentation of the LLC with additional cartilage grafting is required (i.e., alar contour graft or lateral crural strut graft).

Nasal Deformities in the Newborn with Bilateral Cleft Lip and Palate (Fig. 38-31)

- The columella is short, but there is a wide variation in this feature among individuals.
- The nasal tip is flat and broad, and it appears bifid.
- The nasal alae are flat and wide. From a worm's-eye view, the alar rims appear to be "S"-shaped.
- The base of the alae on each side are displaced laterally and sometimes inferiorly and posteriorly.
- Both nostrils are horizontally oriented.
- The LLCs are typically severely buckled and deformed. The medial crura are short and widely separated at the nasal tip. The lateral crura are flat and elongated.
- The dome of the nasal tip is angled obtusely.
- The nasal floor is clefted (open).
- The columella, the caudal end of the septum, and the anterior nasal spine are displaced anteriorly as a reflection of the forwardly projected premaxilla.
- The nasal tip and the nostrils may be asymmetric as a reflection of the displaced premaxilla.

Basic Nasal Reconstructive Maneuvers for the Primary Bilateral Lip Repair (Figs. 38-32 and 38-33)

- The philtral flap is raised as part of the primary bilateral lip repair. Circulation to the philtral flap is based on attachment to the columella soft tissues. Elevation of the medial and lateral nasal soft-tissue flaps for nasal sill and floor reconstruction is carried out after the philtral skin flap is accomplished (Fig. 38-32, *B,C*).
- Along the lateral aspect of the nose, the nasal soft tissues (including the inferior turbinate) are released from the pyriform rim and the lateral nasal wall with the use of an elevator (Fig. 38-33, *A*).
- Next, the buckled and flattened lateral crus of the LLC is released from the overlying nasal soft tissues with the use of Stevens scissors (Fig. 38-33, *B*).
- The elevated lateral nasal flap (including the inferior turbinate) will be advanced medially, superiorly, and anteriorly to facilitate nasal sill and floor reconstruction (Fig. 38-32, *D*).
- Along the medial aspect of the nose, the nasal soft tissues (including the medial crus of the LLC) are released from the anterior nasal spine and septal cartilage with the use of an elevator and Stevens scissors. The elevated medial nasal flap will be advanced laterally to facilitate nasal sill and floor reconstruction) (Fig. 38-33, *C*).
- The release of the orbicularis oris muscle from its abnormal bone and soft-tissue attachments is accomplished with the use of Stevens scissors. Reconstruction of the orbicularis oris muscle with interrupted sutures achieves continuity across the lip. Just before muscle approximation, gentle mechanical (orthopedic) "thumb" pressure can be applied to the premaxilla if needed to improve its position. Reasonable alignment of the premaxillary segment just before repair is preferred to achieve a tension-free soft-tissue lip closure (Fig. 38-32, *D*).
- Recurrent buckling of the lateral crus of the LLC early after surgery is limited by the placement of a stent (i.e.,

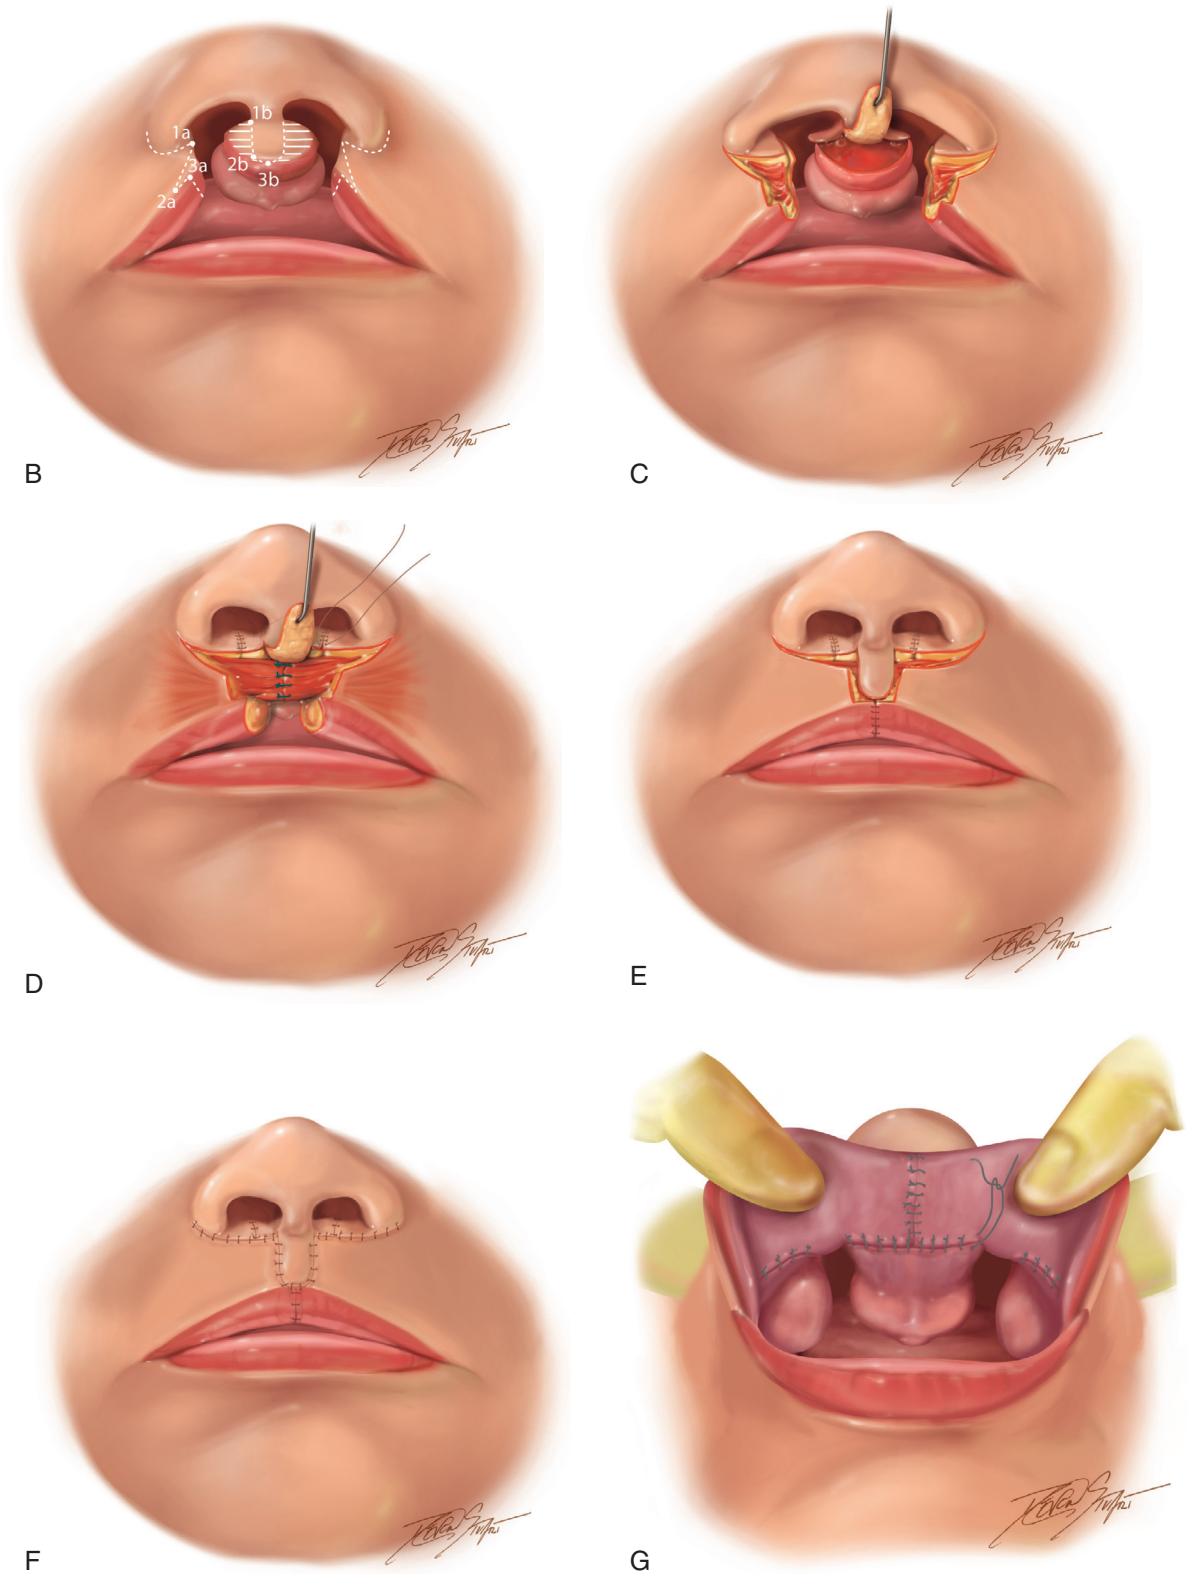
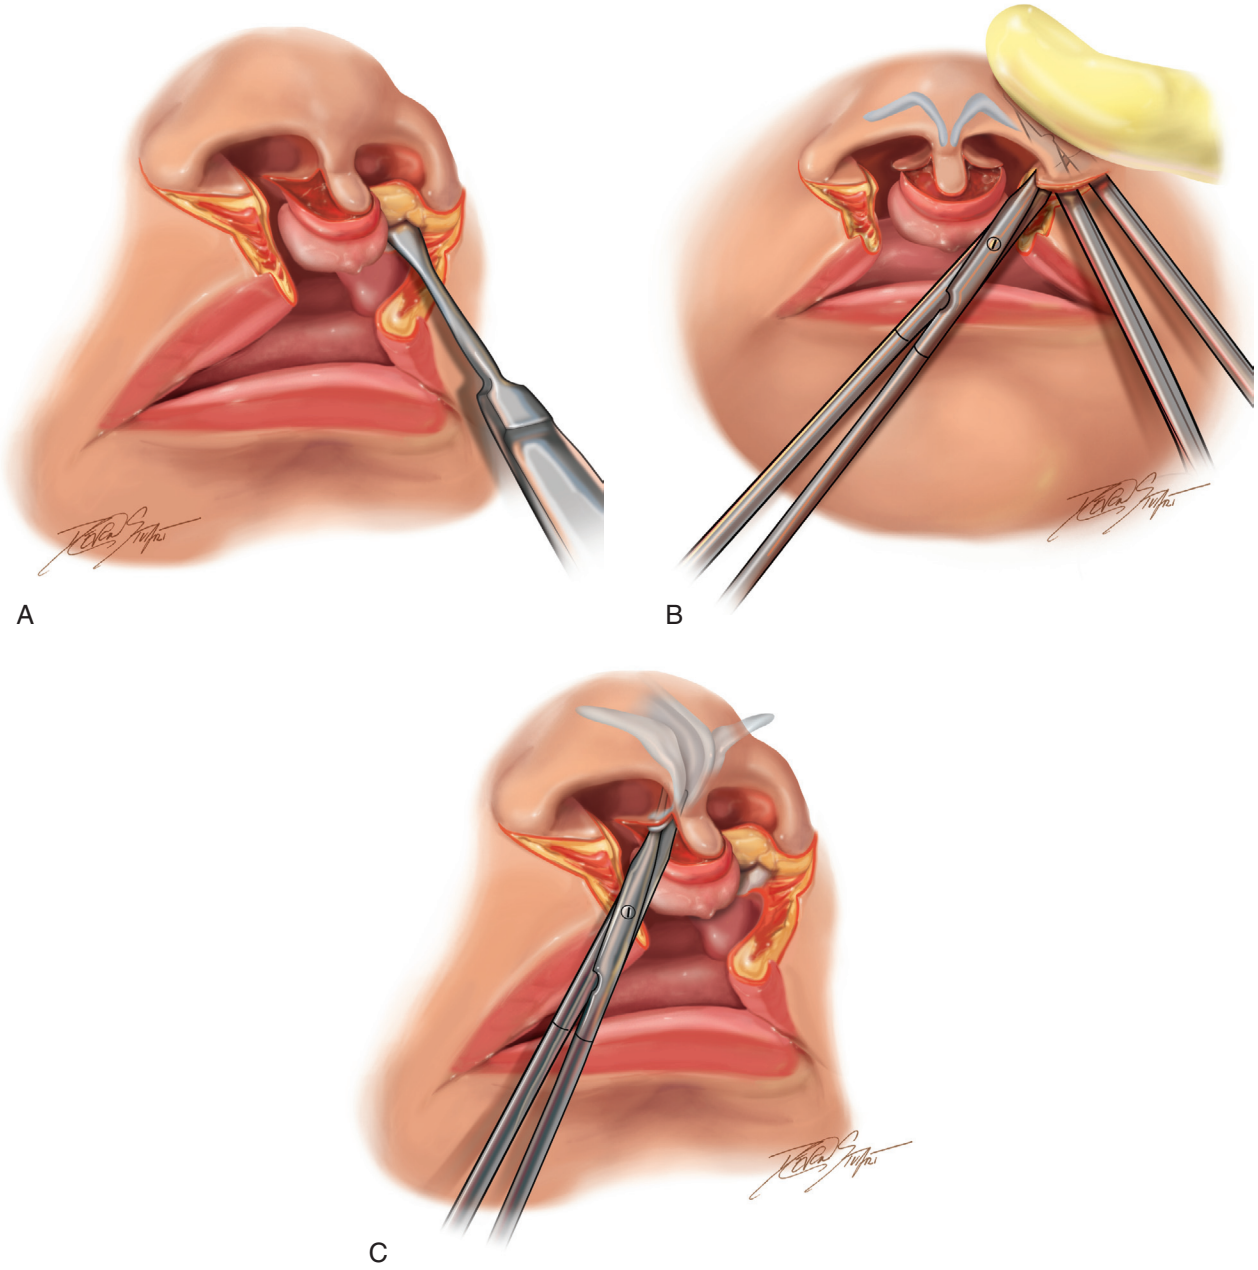
A

• **Figure 38-32 A,** Illustration of typical facial malformations and distortions in a newborn with complete BCLP.

Continued



• **Figure 38-32, cont'd** **B** and **C,** Illustrations of the basic technique used by this surgeon for primary bilateral cleft lip reconstruction. In **B,** the incisions are indicated *(dotted lines)*, with redundant tissue to be excised shown *(diagonal lines)*. In **C,** the philtral skin flap has been elevated with circulation maintained through the soft tissues of the columella. The lateral lip flaps include vermilion–mucosa soft-tissue extensions to be used for the reconstruction of the central red lip. The orbicularis oris muscle has been dissected free of its abnormal bony and soft-tissue attachments and also released from the overlying lip skin. The medial and lateral nasal floor flaps have already been elevated within each nostril (see Fig. 38-33). **D,** The orbicularis oris muscle is then approximated across the midline and sutured together at the columella base. Just before muscle approximation, gentle mechanical orthopedic "thumb" pressure can be applied to the premaxilla if needed to improve its position. Improved alignment of the premaxillary segment just before repair will allow for a tension-free soft-tissue lip closure. The anterior portion of the nasal floor is then reconstructed on each side by suturing the advanced medial and lateral nasal floor flaps. **E,** The vermilion–mucosa extensions of each lateral lip flap are approximated and sutured in the midline to create the vermilion–mucosa junction. **F,** The philtral flap is aligned with the advanced vermillion extensions of the lateral lip flaps (i.e., the vermilion–cutaneous junction) and sutured in place. The cutaneous layer of each lip flap is advanced and sutured first at the columella base and then at the vermillion on each side. The philtral columns and the nasal sills are sutured. **G,** The intraoral mucosa is aligned to establish a functional vestibule. Excision of redundant red lip was initially accomplished just after elevating the philtral flap. The lip side of the vestibule is reconstructed with mucosa from the advanced lateral lip flaps. The alveolar side of the vestibule is reconstructed with the retained mucosa on the premaxillary segment. Note: Alveolar clefts and fistulas remain.



• **Figure 38-33** Illustrations of the bilateral cleft nasal maneuvers that are carried out as part of the primary repair. **A,** Along the lateral aspect of the nose, the nasal soft tissues (including the inferior turbinate) are released from the pyriform rim, and the lateral nasal wall is released with an elevator inserted through the open lip. **B,** Next, the buckled and flattened lateral crus of the lower lateral cartilage is released from the overlying nasal soft tissues with a Stevens scissors inserted through the open lip. The elevated lateral nasal flap (including the inferior turbinate) will be advanced medially, superiorly, and anteriorly to facilitate nasal floor reconstruction. **C,** Along the medial aspect of the nose, the nasal soft tissues (including the medial crus of the lower lateral cartilage) are released from the anterior nasal spine, and septal cartilage with the use of a Stevens scissors inserted through the open lip. The elevated medial nasal flap will be advanced laterally to facilitate nasal floor reconstruction. Recurrent buckling of the lateral crus is limited early after surgery with the use of an intranasal stint (packing) in each nostril. Sutures through the nasal soft tissues are also placed to pexy each lower lateral cartilage.

packing) in each nostril. Sutures through the nasal soft tissues and LLCs on each side may also be used to elevate and maintain the shape of the nasal rims.

Two typical patients with bilateral cleft lip and palate (BCLP) who have been treated with the use of the techniques described are shown after primary lip and nasal repair (Figs. 38-34 and 38-35). Pre-BCLP lip-repair maneuvers have been described in the literature for the purpose of repositioning a protrusive premaxilla and to improve nasal anatomy. They include: taping; the use of a nasoalveolar molding device; the use of a Latham pinning device; lip adhesion; and the application of gentle direct mechanical (orthopedic) backward pressure on the premaxilla.[2,26,78,117,229,244,153] Each of these maneuvers has its strong advocates and its vocal detractors. Despite decades of dispute and discussion, standards of care that involve this important cleft reconstruction topic remain limited.[172]

Residual Nasal Deformities in the Adolescent and Adult with Repaired Bilateral Cleft Lip and Palate

Residual nasal deformities in the adolescent or adult with repaired BCLP include any uncorrected features of the primary malformation that may be compounded by previous surgical maneuvers and ongoing unfavorable nasomaxillary growth. Lesser degrees of the malformation will be seen in the adolescent and adult depending on the success of primary nasal reconstructive maneuvers. The most favorable rhinoplasty results are achieved only after deformities of the underlying maxillary skeleton (i.e., the floor of the nose, the piriform rims, and the anterior nasal spine [e.g., maxillary hypoplasia]) are first reconstructed. It is now clear that, for a majority of individuals with repaired BCLP, orthognathic procedures will be required to correct baseline facial disharmony before definitive rhinoplasty (see Chapter 33).

Orthognathic Surgery; J.C. Posnick

• **Figure 38-35 A,** A newborn girl with complete BCLP is shown. At the time of primary cleft lip repair, she underwent nasal reconstructive maneuvers as described in the text (see Figs. 38-32 and 38-33). **B,** She is next shown just 1 week after primary lip and nasal reconstruction. **C,** She is then shown at 1 year of age just before cleft palate repair. Note the decreased height of the columella that is part of the malformation; she will require definitive nasal reconstruction with the use of an open technique and a rib cartilage caudal strut during the early teenage years (Fig. 38-36).

Residual BCLP nasal deformities in the adolescent or adult that frequently require correction include the following:

- A short columella and a lack of caudal projection of the inferior aspect of the septum
- The flattening of the osseocartilaginous vault
- Nasal tip bifidity
- The buckling of the downward rotation of the LLCs
- The lateral displacement of the alar bases that results in the horizontal rotation of the nostrils

In addition to the usual open rhinoplasty maneuvers carried out in the adolescent or adult with a repaired BCLP, the short columella defines the deformity.[178,221,253] Correction of the short columella in a patient with BCLP is preferably accomplished with the use of a crafted autogenous rib cartilage caudal strut graft. This option is an effective method to provide structural support for the stretching of the columella skin and the nasal soft-tissue envelope over the graft to achieve needed projection (Figs. 38-36 through 38-39). The rib cartilage graft is stabilized to the base of the maxilla with a no. 35 threaded Kirschner wire (K-wire). After modification, the LLCs are sutured together and over to top of the rib cartilage caudal strut to form the superficial aspect of the new tip (Fig. 38-40).

The American Cleft Palate–Craniofacial Association parameters of care document that addresses secondary cleft lip nasal reconstruction includes only the following statements[172]:

- Although rhinoplasty and nasal septal surgery are usually advocated only after the completion of nasal growth, earlier intervention for reasons of airway problems or nasal tip deformity may be indicated.
- The repair of the cleft lip nasal deformity can be accomplished with limited external incisions on the nose.
- The timing of nasal surgery should be discussed with the patient and the family so that the goals are understood and the expectations are realistic.
- The patency of the nasal airway should be considered when planning either nasal reconstructive procedures or secondary velopharyngeal operations (e.g., a pharyngeal flap, another type of pharyngoplasty).

Until clear parameters regarding the timing and technique of secondary cleft nasal surgery become available, individual surgeon experience and personal preferences will remain standard practice. Unfortunately, this can easily lead to frustration and miscommunication among the patient, the family, and the treating clinicians.

Timing of Definitive Cleft Nasal Reconstruction

To maximize long-term nasal breathing, adequate sinus drainage, and the enhancement of facial aesthetics, a definitive cleft rhinoplasty should only be undertaken after successful alveolar bone grafting, including the stabilization of the premaxilla in the case of BCLP and fistula closure. If orthognathic corrections are required, then definitive nasal reconstruction is best delayed until at least 6 months after successful skeletal reconstruction. Recent studies conducted at both Boston Children's Hospital and the Hospital for Sick Children in Toronto, Ontario, Canada, confirm that approximately 50% of adolescents and adults with UCLP and 65% to 77% of adolescents and adults with BCLP will require orthognathic surgery. The correction of the cleft jaw deformity is preferably carried out when the patient is between 15 and 18 years old and before graduation from high school (see Chapters 32, 33, and 34).

NOTE: This author does not favor repetitive limited rhinoplasty maneuvers performed throughout childhood. Although they are well intended, nasal procedures carried out after the primary repair but before definitive reconstruction may result in additional scarring and distortions that will limit long-term aesthetic and functional airway results.

Congenital and Posttraumatic Saddle-Nose Deformities

The hallmark of most *congenital and posttraumatic saddle-nose deformities* is the deficiency of both the *osseous and cartilaginous vaults.* The surgical correction of a saddle-nose deformity was first described by Robert Weir in 1889, when he wrote a report entitled "Restoring Sunken Noses." He implanted the breastbone of a freshly killed duck below the skin of a severely shrunken nose in a young syphilitic patient as a means of reconstruction.[250] In current times, a frequent form of saddle nose results from either congenital deformity (e.g., bifid cleft nose, Binder syndrome, cranio–fronto–nasal dysplasia; Figs. 38-41 through Fig. 38-44) or from an acquired postnasal fracture cause (e.g., complex naso–orbito–ethmoid fractures, direct low-velocity trauma to the nasal bones in the growing child; Fig. 38-45).[184] The congenital and posttraumatic saddle nose as defined includes the deformity of the osseous vault (i.e., the nasal bones) and the cartilaginous vault (i.e., the quadrangular cartilage). These saddle-nose deformities generally present with an acceptable soft-tissue envelope and nasal lining. They also generally have an intact septum (i.e., no septal perforation). The reconstruction required for these saddle-nose deformities will vary with their cause (e.g., cocaine related, autoimmune conditions, iatrogenic postseptoplasty-induced "depressed" nose).* The postseptoplasty saddle-nose deformities present with an intact osseous vault but with significant septal perforations that result in a depressed cartilaginous vault; this is discussed later in this chapter.

• **Figure 38-36** A child was born with complete BCLP. She underwent two attempts at cleft lip repair at another institution that resulted in wound dehiscence and necrosis of the philtral soft tissues. This was likely the result of a combination of factors, including the following: 1) a protrusive premaxilla before repair; 2) inadequate release of and then repair of the orbicularis muscle; 3) and the incisions used to elevate the philtral flap. She was referred to this surgeon and then underwent successful lip reconstruction that included gentle mechanical and orthopedic "thumb" pressure on the premaxilla just before approximation of the orbicularis oris muscle. This was followed by palate repair with the use of the Bardach two-flap technique when she was 14 months old and then successful bone grafting during the mixed dentition. During the patient's early teenage years, there was harmonious growth and adequate sagittal projection of both jaws. The teeth were orthodontically aligned, with closure of the cleft–dental gaps. The cleft nasal deformity was characterized by a short columella and a wide depressed tip. The soft-tissue deficiency of the upper lip (philtrum) remained as a result of necrosis during infancy. A decision was made to not construct an Abbe flap, which would scar the lower lip and result in a "patch" (color mismatch) with the upper lip. An open rhinoplasty was carried out that included modification of the lower lateral cartilages and rib cartilage caudal strut grafting with stretching of the nasal soft tissues to create improved tip position and shape. Composite resin buildups and contouring of the hypoplastic anterior maxillary teeth were carried out by a restorative dentist after definitive nasal reconstruction. **A,** The patient is shown at 4 months of age, when she was referred to this surgeon, and at 14 years of age after successful lip and palate repair during infancy, bone grafting during the mixed dentition, and just before the removal of the orthodontic appliances and definitive nasal reconstruction. **B,** Oblique facial views before and at 15 years of age after nasal reconstruction. **C,** Profile views before and at 15 years of age after nasal reconstruction.

• **Figure 38-37** A teenage girl of Arabic descent was born with complete BCLP. She has been managed by this surgeon since birth. She underwent primary lip and nasal repair and palate reconstruction during childhood and then successful bone grafting during the mixed dentition. She required the correction of a cleft jaw deformity when she was 15 years old. The procedures included maxillary Le Fort I osteotomy; sagittal split ramus osteotomies; osseous genioplasty; septoplasty, inferior turbinate reduction, and nasal floor recontouring. Six months later, the patient underwent definitive nasal reconstruction to correct a wide nasal bridge and a depressed tip. Her open rhinoplasty included nasal osteotomies (in-fracture and straightening); dorsal reduction (bone and cartilage); and nasal tip maneuvers (modification of the lower lateral cartilages and rib cartilage caudal strut grafting). **A,** Frontal views before and after cleft orthognathic and nasal reconstruction. **B,** Oblique views before and after cleft orthognathic and nasal reconstruction. **C,** Profile views before and after cleft orthognathic and nasal reconstruction.

• **Figure 38-38** A teenage Hispanic male was born with complete BCLP. He underwent lip and palate repair and ineffective bone grafting during the mixed dentition by another surgeon. When referred to this surgeon, he presented with maxillary hypoplasia, mobile premaxilla, cleft dental gaps, residual fistula, and alveolar clefts. He underwent maxillary Le Fort I osteotomy in three segments and osseous genioplasty. Six months later, he underwent definitive rhinoplasty to manage residual and secondary cleft deformities, including a wide bridge, a depressed nasal tip, and difficulty breathing (see Fig. 33-10). His open rhinoplasty included nasal osteotomies (in-fracture and straightening); dorsal reduction (bone and cartilage); nasal tip maneuvers (modification of the lower lateral cartilages and rib cartilage caudal strut grafting); septoplasty; and inferior turbinate reduction. **A,** Frontal views before and after reconstruction. **B,** Profile views before and after reconstruction.

• **Figure 38-45, cont'd F,** Close-up lateral views of the nose just before surgery and at 6 months and then 16 years after reconstruction.

Surgical Approach to the Combined Collapse of the Osseous and Cartilaginous Vaults

Surgical attempts to correct the postseptoplasty pattern of saddle-nose deformity have been reported for at least the past century. McDowell and colleagues discussed the multiple heterogeneous implant methods used during his time, which included inorganic materials (e.g., gold, silver, tin, thallium, Vitallium, plastic, silicone) and organic implants (e.g., ivory, cartilage, bone, fibrin, fascia).[138] Fomon and colleagues described the use of autogenous materials for the restoration of nasal contour (i.e., fat, dermis, cartilage, and bone).[64] Historically, local transposition flaps were often recommended to augment the internal (mucosa) lining or the external (skin) cover. By the 1950s, most clinicians agreed that individuals who presented with marked depressions of the cartilaginous and bony dorsum required firm, deep, layer grafts or implants. Surgical reconstruction is now thought to require grafting from the radix to the tip and often from the tip down to the base of the maxilla. Today, autogenous tissue is generally used, but donor-site preference, fixation techniques, and how the graft holds up at the recipient site remain important questions.

Posttraumatic saddle-nose deformities of the bony vault often result from displaced fractures with secondary collapse after incomplete reduction (see Fig. 38-45). In addition, a crush injury to the nose during early childhood will result in impaired growth and progressive deformities. Another subgroup of patients with saddle-nose deformity presents during adolescence with congenital nasal and dentofacial anomalies (see Fig. 38-41). Whatever the cause, the end result is a flattened, splayed, and sometimes asymmetric osseous vault in combination with a depressed cartilaginous vault. The trauma event or the congenital anomaly also leads to ULC and LLC displacement with poor tip projection, flaring of the alae, widening of the domes, and rounding of the anterior nares. The extensive traumatic or congenital anomalies that caused the saddling of the cartilaginous and osseous vault will also result in mechanical nasal airway obstruction. When this occurs during childhood, the forced oral respiratory pattern with a constant open-mouth posture often results in a long face growth pattern over the ensuing years (see Chapters 4 and 21).

The correction of a severe saddle-nose deformity of the bony and cartilaginous vaults requires the insertion of a deep dorsal graft from the radix to the tip that is ideally constructed from either autogenous cartilage or autogenous bone (see Fig. 35-45). Rib cartilage has advantages over bone in that it restores flexibility to the cartilaginous vault and tip, it is often considered easier to harvest, and it is less prone to resorption. It has the disadvantages of having a tendency to warp, not adhering to the underlying osseous vault, and not replacing like for like over the osseous vault. Autogenous bone (e.g., calvarial, iliac, rib) has the advantages of ease of crafting, adherence to the underlying basal bone when properly immobilized (fixed), and replacing like for like tissue over the osseous vault. It has the disadvantages of requiring more complex donor site harvesting, having a tendency for partial resorption, and resulting in a firm nasal tip that is prone to fracture. Whether autogenous cartilage or bone is used to correct the osseous and cartilaginous vaults, reliable reconstruction requires satisfactory skin

cover, internal nasal lining, and LLCs that can be pexied over the graft to form the superficial aspect of the new nasal tip.

Autogenous graft options to consider include the following:

1. *Rib costochondral graft (radix to tip).* This is combined with a separate rib cartilage caudal strut graft that extends from the base of the maxilla (stabilized with a K-wire). It is then secured with sutures to the dorsal costochondral graft at the tip. The LLCs are sutured over the grafts to form the height of the new nasal tip.
2. *Rib cartilage graft (radix to tip).* A no. 35 K-wire may be inserted through the dorsal strut graft to prevent warping. The dorsal graft is combined with a separate rib cartilage caudal strut graft that extends from the base of the maxilla (stabilized with a K-wire). The caudal graft is then secured with sutures to the dorsal strut rib cartilage graft at the tip. The LLCs are sutured over the grafts to form the height of the new nasal tip.
3. *Calvarial graft (radix to tip).* The crafted calvarial bone graft is firmly secured with K-wires or titanium plates and screws to the underlying nasal bones. The LLCs are sutured over the graft to form the height of the new nasal tip.
4. *Iliac graft (radix to tip).* The crafted iliac graft is firmly secured with a K-wire or titanium plates and screws to the underlying nasal bones. The LLCs are sutured over the graft to form the height of the new nasal tip. Extension of the bone graft into an "L" shape as a caudal strut may be done to limit the fracture and resorption of the dorsal strut.

Cocaine-Related and Autoimmune and Iatrogenic Saddle-Nose Deformities

The hallmark of most *cocaine-related, autoimmune, and iatrogenic saddle-nose deformities* is significant *septal perforations* that result in *deficiency (depression) of the cartilaginous vault,* generally with an intact osseous vault (Fig. 38-46).

Cocaine is an alkaloid that was originally used by South American Indians as a stimulant. It was introduced to medicine by Koller in the 1880s as a local anesthetic.[119] The recreational use of cocaine is a common form of drug abuse throughout the world. At least 30 million Americans are estimated to have used cocaine at least once (i.e., 20% of the adult population), and 6 million use it with some regularity (i.e., once a month or more).[56] It is estimated that approximately 20% of users become addicted. The most commonly used route of administration for the drug is intranasal inhalation or "snorting."[58] Cocaine's intense local vasoconstrictive effects and mucosal irritation from substances with which it is "cut" (e.g., talc, mannitol, lactose, amphetamines, borax, plaster of Paris) may lead to inflammation and ulceration of the nasal mucosa.[66,227] Permanently exposed septal cartilage in combination with bacterial overgrowth will lead to osteochondritis and further necrosis and perforations, thereby resulting in the loss of structural support and the collapse of the nasal dorsum.[19,246] Less common but reported complications in the sinonasal region after cocaine abuse include oronasal fistulas, palatal destruction, and even complete midface necrosis.[216,224,228] All reported cases of palatal perforations from cocaine insufflation initially presented with a limited perforation of the nasal septum followed by progressive destruction of the associated structures.[7,14,65,71,87,134,212,242]

The adverse effects of cocaine on the nasal structures were first systematically reported by Owens in 1912.[167,170] He described a range of cocaine-induced deformities, from a pinhole perforation to progressive degrees of mucosal ulceration, destruction of the septal cartilage, and, in extreme cases, the destruction of the nasal and maxillary bones. When a nasal septal perforation is small and anterior, it can cause a disconcerting whistle during breathing. When the hole is larger and more posterior, as it is in most individuals who present for the surgical evaluation of a saddle nose, it will have destroyed most of the septal cartilage.[145] Businco and colleagues reported on a series of 104 patients who habitually inhaled cocaine more than 10 times per month.[22] They were observed for at least 2 years. Among them, 11 patient (11%) had nasal septal perforation. Of these 11 patients, 8 had nasal septal perforation of just the quadrangular cartilage; in the other 3, the perforation also involved the bony tract (i.e., the vomer-perpendicular ethmoidal lamina).

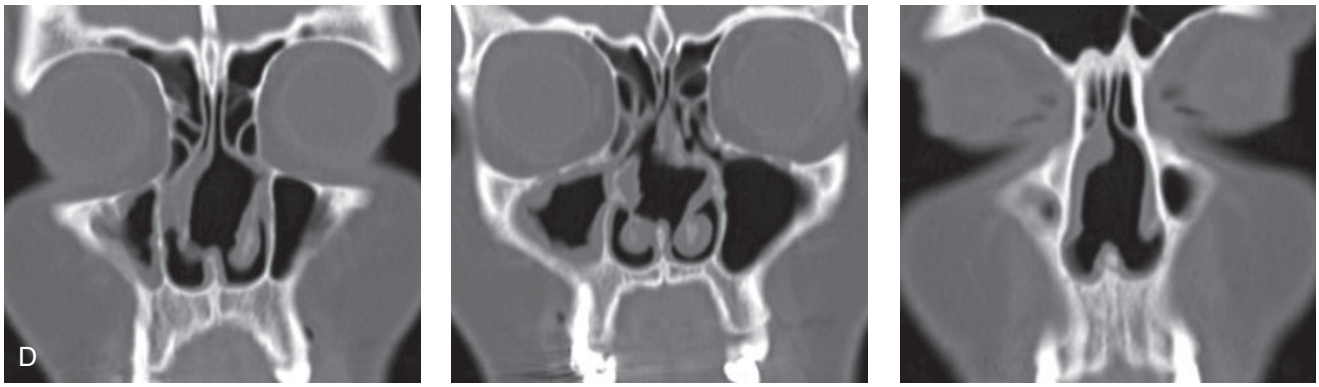
Over the years, the management of cocaine-induced septal perforations has included the placement of "buttons" to block the defect; the use of local nasal mucosal flaps; the use of regional nasolabial flaps; and the use of distant microvascular repairs.[28,56,120,122,132,140,154,155,158,171,204] The flap options, even when they effectively close the perforation, typically obstruct normal function of the airway as a result of their bulk. This author in agreement with most clinicians that, until a safer and more reliable vascularized and thin flap is found and proven to be effective, it is generally best to maintain good nasal hygiene and not attempt perforation closure.[143]

Similar septal perforations and secondary saddle deformities of the cartilaginous vault are sometimes seen after overly aggressive surgical submucosal resections that have been carried out to relieve nasal obstruction or after postoperative or posttraumatic hematoma or infection (see Fig. 38-46).

The same pattern of saddle-nose deformity is frequently observed in patients with *Wegener granulomatosis*.[8,61,159] This is a rare multisystem autoimmune disease of unknown etiology. Its hallmark features include necrotizing granulomatosis, inflammation, and pauci-immune vasculitis in small and medium-sized blood vessels. In 1897, Peter McBride gave the first written description of a patient

• **Figure 38-46** A middle-aged woman of Arabic descent with a postsurgical (iatrogenic) saddle-nose deformity. Two years earlier, she underwent an aggressive septoplasty procedure at another institution. This resulted in a large septal perforation with the collapse of the cartilaginous vault. She arrived for evaluation and then underwent nasal reconstruction that included rib cartilage grafting with caudal and dorsal struts as described in text. **A,** Frontal views before and after reconstruction. **B,** Oblique views before and after reconstruction. **C,** Profile views before and after reconstruction.

Continued



• **Figure 38-46, cont'd D,** Computed tomography sinus scan views (coronal cut) that confirm the extent of the septal deficits before reconstruction.

with this condition.[145] Thirty-four years later, Klinger described a 70-year-old physician with joint symptoms, proptosis, widespread upper respiratory tract inflammation that led to saddle-nose deformity, glomerulonephritis, and pulmonary lesions.[145] In 1936, Wegener described three patients with similar clinical features and published his findings.[145] The prevalence of Wegener granulomatosis in the United States is estimated to be 3 cases per 100,000 people. Chronic sinusitis is the most common initial complaint, with approximately 60% to 70% of cases involving a failure to respond to conventional treatment. The Wegener granulomatosis saddle-nose deformity is caused by the perforation of the posterior aspects of the quadrangular cartilage with a loss of dorsal support. When the autoimmune disease is in remission and the need for medications that affect wound healing is no longer present, then reconstruction of the collapsed nasal cartilaginous vault can go forward as described in the following section.

Surgical Approach to the Collapsed Cartilaginous Vault

Before the reconstruction of a collapsed cartilaginous vault, the surgeon must assess the presenting nasal anatomy, including all defects and their effects on function.* More than half a century ago, Millard pointed out that, in these cases—despite the apparent overwhelming "destruction of the nose"—the covering skin is generally intact and unscarred, and it can be salvaged to serve as the final nasal cover.[145] It is also recognized that, in most cases, the nasal bones, the pyriform rims, and the floor of the nose are unaffected. The same is true for the LLCs and the ULCs. A full-thickness nasal septal defect that involves much of the quadrangular cartilage and overlying mucosa and that extends inferiorly toward the nasal floor and posteriorly toward the vomer is typical (see Fig. 38-46, *D*).

*References 7, 28, 56, 61, 63, 64, 71, 95, 96, 119, 120, 122, 132, 154, 175, 180, 221, 230, 247, 251

As part of the reconstruction, the bony dorsum may benefit from surgical reduction if there is a true "hump"; however, augmentation is rarely indicated. In general, nasal osteotomies are avoided unless they are absolutely required (i.e., a crooked bony vault as a result of previous nasal fracture or surgery or excessive widening of the bridge caused by hereditary tendencies). The ULCs and the LLCs, although flattened, rarely require replacement. During the operation, these cartilages are dissected from the overlying skin cover via an open approach and then repositioned as needed. The cephalic portions of the LLC may be conservatively excised. The middle crura are separated down to the base of the maxilla and the anterior nasal spine region but without continuing the dissection more posterior, which would expose the septal perforation.

Typically, a rib cartilage graft is harvested and crafted into two struts to be used for the reconstruction (see Chapter 18) (Video 10). The first is a *caudal strut* of approximately 25 to 30 mm in length that extends from the base of maxilla to the new nasal tip (see Fig. 38-40). The second is a *dorsal strut* of approximately 35 to 40 mm in length that is notched and inset deep to (only ≈2 mm) and then flush with the nasal bones before extending to the tip. The grafts are secured to each other at their points of insertion and then to each other where they join at the tip. The LLCs are sutured over the top of the grafts to form the most superficial aspect of the nasal tip. The soft-tissue envelope is then redraped over the new cartilaginous vault and tip.

Reconstruction of a Collapsed Nasal Cartilaginous Vault: Step-by-Step Approach

- General anesthesia is given through orotracheal intubation. The endotracheal tube is secured to the chin region with tape.
- Local anesthesia (Xylocaine 1% with 1:100,000 epinephrine) is injected for hemostasis below the soft-tissue envelope of the nose.
- An open technique is used. Stair-step columella (skin) and bilateral marginal (intranasal) incisions are completed.

- The overlying cutaneous soft-tissue envelope is elevated up the columella, superficial to the LLCs and ULCs, subperiosteal over the nasal bones to the radix, and laterally toward the maxillary process on each side. The fully elevated soft-tissue envelope will later be advanced caudally over the reconstructed cartilaginous vault and nasal tip at wound closure.
- The elevated mucosa lining is protected throughout the dissection without perforation into the nasal cavity.
- Dissection also extends under the nasal bones (≈5 mm) for later insertion (i.e., tongue and groove) of the dorsal strut graft.
- If a dorsal bony "hump" requires reduction, this is conservatively completed with rasps.
- The medial crura are separated from each other via scissors dissection down to the base of the maxilla and the anterior nasal spine. This is accomplished without perforation through the mucosal lining into the nasal cavity.
- The deficient dorsal and caudal portions of the quadrangular cartilage are reconstructed with rib cartilage that has been crafted into two separate struts. After the struts are secured at their points of origin, they are sutured together to form the new tip and to serve as a replacement for the deficient cartilaginous vault.
- The caudal strut graft extends from the base of the maxilla (i.e., the anterior nasal spine region) and then up to the new nasal tip; this graft is approximately 25 to 30 mm in length. It is secured to the base of the maxilla with a no. 35 threaded K-wire that has been drilled into the anterior nasal spine region for a depth of approximately 5 mm. If there is perforation through the palatal mucosa, the K-wire is backed out. The K-wire is cut, with an extension of several millimeters left above the exposed base of the maxilla. The caudal strut graft is then pierced into the K-wire to prevent the movement of the graft during the healing process.
- The dorsal strut graft is notched via a tongue and groove to extend several millimeters deep to the nasal bones and then flush with the osseous surface that extends caudal to the new nasal tip; the graft is approximately 35 to 40 mm in length. It is positioned either in between or on top of the ULCs and then sutured in place to limit movement during healing.
- The dorsal strut graft meets the caudal strut graft at the tip. The two grafts are further crafted using a knife (no. 15 blade) to form the new nasal tip. They are secured together with several interrupted non-resorbable sutures (4-0 Prolene).
- The LLCs, having been trimmed of any cephalic excess, are sutured together and then over the strut grafts to form the most superficial aspect of the nasal tip (4-0 Prolene).
- One of the challenges is the management of any scar contracture of the mucosa lining, which may limit the caudal and anterior advancement of the LLC for suturing over the grafts. This is managed by the following:
  - The dissection and release of the nasal lining, but without perforation
  - If necessary, the reduction of the height of the strut grafts (i.e., the new nasal tip) to accommodate any intrinsic soft-tissue limitations
- The dorsal and caudal strut grafts can be reinforced with an internal no. 35 threaded K-wire to limit the risk of warping. The decision to do so must be made before inset and before the grafts are secured in place.
- The stair-step columella (skin) incision is closed with one deep layer stitch (5-0 Vicryl). The closure of the skin layer is accomplished (6-0 nylon), and the rim incisions are closed with resorbable sutures (5-0 chromic).
- Antibiotic ointment (Bactroban) is injected into the nasal cavity. Gentle packing in each nostril (Telfa) is carried out to decrease intranasal swelling and bleeding.
- Tape is placed over the dorsal skin (Steri-Strips).
- A custom splint (Aquaplast) is conformed over the dorsum.
- The packs are removed after 48 hours.
- The dorsal splint is removed after 5 to 7 days.

The reconstructive outcomes for cocaine-related, autoimmune, and iatrogenic cartilaginous vault collapse may not be perfect, but they should provide a relatively normal nasal form, often with an improved airway. The presenting septal perforations will remain. The dorsal and caudal support for the external nose that was deficient should be restored without the need for replacement of the soft-tissue envelope. The goal is for the individual to become socially presentable without excessive attention being drawn to the previous nasal deformity. This should be possible with a single-stage reconstruction without extensive donor-site scarring or disability in most patients.

Conclusions

Successful rhinoplasty is accomplished after the obtaining of an accurate patient history; the performance of a thorough head and neck examination that includes the intranasal cavity; and the completion of a facial aesthetic analysis. This is followed by engaging in a frank discussion with the patient and the family about the treatment objectives; the quality of the individual's skeletal and soft tissues; what is technically possible; and an appreciation of the individual's overall facial proportions. When combining sound clinical judgment, technical expertise, and safe conditions, the surgeon may perform precise functional and aesthetic rhinoplasty with a predictable level of patient satisfaction. Relieving nasal obstruction to improve breathing and achieving an aesthetically pleasing nose that preserves the individual's uniqueness through a combination of reduction and augmentation techniques remain the clear objectives.

Patient Education Materials

Rhinoplasty (Reshaping the Nose) Surgery

A rhinoplasty surgical procedure may be designed to improve the appearance of the nose, to correct nasal breathing, or both. The operation usually requires about 1.5 hours, and it is performed on an outpatient basis with the patient under anesthesia. An additional several hours are spent in recovery before the patient is discharged home. A customized splint is applied to the outside of the nose, and packing material is often placed inside. There will be some discomfort for which pain medication is prescribed. Antibiotics will be given just before surgery and continued at least until the packing is removed.

Discoloration and swelling occur in the cheeks and the eyelid region. The swelling gradually disappears, although inadvertent trauma or sunburn may cause it to persist a great deal longer. The tip of the nose is usually numb for several months after surgery, but this too improves with time.

The final results after rhinoplasty are not fully apparent for 6 to 12 months, at which point the nasal swelling has subsided. For some patients, after rhinoplasty, there are dramatic changes; for others, the improvements may be more subtle. Nasal surgery is an art and a science, but it is not magic. Your surgeon will try to preserve the positive characteristics that make your nose unique while modifying the aspects that distract from your appearance. The goal will be to modify specific undesirable characteristics to achieve a more harmonious balance of nasal and facial features given your specific anatomic limitations. In general, aesthetic judgments will be conservative. When it comes to rhinoplasty, it is better to remove less than more.

INSTRUCTIONS FOR RHINOPLASTY SURGERY

The purpose of these instructions is to help you to prepare for and then recover from your operation with as little discomfort as possible and to minimize the risk of complications.

Preoperative Instructions

1. For at least 2 weeks before surgery, do not take any aspirin, aspiring-containing products, or aspirin-like products (e.g., ibuprofen). Do not take any medication that may increase bleeding during surgery or bruising afterward.
2. No smoking or nicotine in your bloodstream for at least 2 weeks before and 2 weeks after surgery.
3. Do not eat or drink anything after midnight the night before surgery, not even a sip of water.
4. Starting 2 days before surgery, we request that you shampoo your hair and shower at least once per day. The morning of surgery, you may also shower and shampoo again.
5. Do not apply makeup the morning of surgery, and leave your jewelry at home.
6. Make arrangements for someone to accompany you home from the hospital the day of surgery, because you will not be able to drive yourself.

Postoperative Instructions

1. After discharge from the hospital, eat lightly (mostly liquids). During the first week, avoid eating anything that is difficult for you to chew.
2. Unfortunately, nausea and sometimes vomiting during the first 12 to 24 hours after surgery is not uncommon. If you develop nausea or vomiting, take only clear fluids for the next 12 hours. Resume a normal diet gradually, as tolerated.
3. Apply cold compress intermittently over your eyelids during the first 24 to 36 hours after surgery. By 36 hours after surgery, the maximum facial swelling will have occurred. Cold compresses are of limited value after this time, but they may be applied for comfort, if desired.
4. For the first week after surgery, sleep primarily on your back, with your head elevated on two pillows.
5. As before surgery, do not take aspirin or aspirin-like products (e.g., ibuprofen) for 2 weeks after surgery. You may take Tylenol (acetaminophen) as you wish.
6. For comfort, you may wish to use Vaseline petroleum jelly or any over-the-counter antibiotic ointment around the nostrils to keep them from drying out. Do not insert anything deep inside the nostril. Use and change the dressing beneath your nose as needed.
7. You may shower from the neck down the day after surgery. You should also wash your face and hair, but do not get the nasal splint wet. After the splint has been removed, you may shower and shampoo your hair and face in a more regular way.

8. Take your usual prescription medication as directed and approved by your surgeon beginning the day after surgery.
9. Get lots of rest and don't do anything that requires more than limited physical exertion during the first week after surgery. You may then gradually increase your activity level, but no sports or gym activities may be performed during the next 4 to 6 weeks as per discussion with your surgeon.
10. You may take the prescribed pain medication as directed on the label. Take the antibiotic medications as directed until the supply is exhausted.
11. When you sneeze, try to do so through your mouth. Do not blow your nose for 2 weeks, and only use nasal sprays that have been approved by your surgeon.
12. Do not consume beverages that contain alcohol or drive while taking prescription pain medications.
13. If you wear contact lenses, you may be comfortable enough to resume lens wearing within 48 to 72 hours. In addition, eyeglasses may be adjusted to rest on or just above the splint. After the removal of the splint (i.e., 5 to 7 days after surgery), you should avoid letting your glasses press heavily on your nose for at least 6 weeks.
14. Make an appointment to see your surgeon on the specified day by calling the office.

Remember the following:

1. Your skin will be noticeably discolored around the eyes and swollen for about 2 weeks. The discoloration will move down your face and neck. The extent of the swelling and discoloration will vary on the two sides of the face. When the nasal packs are removed (approximately 2 days after surgery), further intranasal swelling will occur and create ongoing difficulty with breathing through the nose. This will gradually resolve over several weeks.
2. The shape of your nose will go through its biggest changes during the initial 3 to 6 weeks after surgery, but it will take about 6 months to 1 year before the final swelling subsides. This is especially true for the nasal tip region.
3. Because of the surgery and the need to cover the nasal soft tissues with a splint during the first week, expect peeling of the skin and blocked pores. You may also go through a short period of acne breakouts. Just wash the affected area gently. The condition of your skin will improve over the course of 5 to 10 days and should gradually return to normal.

Director, Posnick Center for Facial Plastic Surgery

Consent for Rhinoplasty Surgery

_____ Initial here

INSTRUCTIONS

This is a document that has been prepared by your surgeon to help educate and inform you about your rhinoplasty surgery and its risks as well as alternative treatment options. It is important that you read this document carefully and completely. Please initial each section on each page to indicate that you have read and understand it. When all of your questions are answered, please also sign the consent for surgery on the last page as proposed by your surgeon.

_____ Initial here

INTRODUCTION

Rhinoplasty (surgery of the nose) is an operation that is frequently performed to produce changes in the appearance, structure, and function of the nose. Rhinoplasty maybe carried out to alter the dorsum (height or width) of the nose; to change the shape of the nose's tip; or to change the angle between the nose and the upper lip. This operation can also help to correct birth defects or nasal injuries and to help relieve breathing problems.

There is not a universal type of rhinoplasty surgery that will meet the needs of every patient. The surgery is customized in accordance with your needs and any specific anatomic limitations. Incisions are generally made within the nose and also into the skin of the nose. Internal nasal surgery to improve breathing can often be performed at the same time.

Continued

Nasal surgery is an art and a science, but it is not magic. Your surgeon must work with your specific tissues (e.g., skin, bone, cartilage, mucosa lining) in an attempt to improve nasal appearance and function. The results of the operation depend on the characteristics and qualities of your specific tissues and on complicating factors such as scarring, tissue deficiencies, and irregularities from previous surgery, injuries, or nature.

No nasal surgery is totally perfect. If you believe that small imperfections in the surgical result will prevent you from appreciating the positives, you should not proceed with rhinoplasty. Every small imperfection cannot be corrected or reoperated on; this approach would lead likely to an "operated" appearance that is unfavorable. Your surgeon will do his or her best to communicate what the planned procedure can and cannot do for you. You are encouraged to ask questions and to openly communicate your concerns.

To reshape a nose, cartilage or other types of grafts may be useful to provide structure and support. Usually these grafts are not visible, but sometimes they can be seen as small bumps or edges through the skin. You may be able to feel them, even if they cannot be easily seen. In some patients, it is possible that cartilage or bone grafts can be partially absorbed by the body or change shape to the extent that they may need to be replaced.

The best candidates for rhinoplasty surgery are individuals who are looking for improvement but not perfection with regard to the appearance of their nose. In addition to realistic expectations, good health and psychological stability are important qualities for a person who is considering rhinoplasty surgery. You must also understand the possible risks and complications and consider the other options available. Rhinoplasty can be performed in conjunction with other procedures (e.g., genioplasty) to enhance your facial appearance.

_____ **ALTERNATIVE TREATMENT**

Initial here Alternative forms of management include not undergoing any surgery at all or considering other more or less extensive nasal procedures. Risks and potential complications are also associated with alternative forms of treatment or surgery and should be considered before you make a decision about the procedure that is right for you.

_____ **RISKS OF RHINOPLASTY SURGERY**

Initial here With any type of surgery, there is inherent risk. An individual's decision to undergo a specific rhinoplasty procedure is based on the comparison of the risk to the potential benefit. Although the majority of patients do not experience the complications detailed below, you should discuss each of them with your surgeon. Be sure that you understand the risks, potential complications, and consequences of the specific rhinoplasty procedure that you intend to undergo.

_____ **BLEEDING**

Initial here It is possible, although unusual, that you will have problems with bleeding during or after surgery. Should postoperative bleeding occur, it may require urgent treatment. Do not take any aspirin or similar anti-inflammatory medications for 2 weeks before and after surgery, because such medications contribute to a greater risk of bleeding. Hypertension (high blood pressure) that is not under medical control may also cause bleeding during or after surgery.

_____ **INFECTION**

Initial here Infection is unusual after rhinoplasty surgery. If an infection does occur, further treatment (e.g., change in antibiotics, drainage, additional procedures) may be necessary.

_____ **SCARRING**

Initial here Although good wound healing after a rhinoplasty procedure is expected, abnormal healing may occur within both the skin and the deeper tissues. Scars may be unattractive and of a different color than the surrounding skin. Additional treatments may be possible to treat scarring.

_____ **DAMAGE TO DEEPER STRUCTURES**

Initial here Deeper structures (e.g., nerves, tear ducts, blood vessels, muscles) may be altered during the course of surgery. The potential for this to occur varies with the type of rhinoplasty procedure performed and your individual anatomy. Injury to the deeper structures may be temporary or permanent.

_____ **UNSATISFACTORY RESULTS**

Initial here The rhinoplasty surgery may result in visible or tactile deformities, loss of function, or structural malposition. You may be disappointed that the aesthetic results of surgery do not meet your expectations. Additional treatment or surgery may be possible should the result be unfavorable for you.

_____ **NUMBNESS**

Initial here There is a potential for permanent numbness within the nasal skin after rhinoplasty. The occurrence of this is not entirely predictable. Diminished sensation in the nasal soft tissues may not totally resolve after rhinoplasty.

_____ **FACIAL ASYMMETRY**

Initial here The human face is normally asymmetric. There can be variations from one side of the face to the other with regard to the results obtained with a rhinoplasty procedure.

_____ **CHRONIC PAIN**

Initial here Chronic pain may occur infrequently after rhinoplasty. The chronic pain or discomfort may be felt on either the inside or outside of the nose.

_____ **SKIN DISORDER/SKIN CANCER**

Initial here Rhinoplasty is a surgical procedure that is performed to potentially reshape both the internal and external structures of the nose. Skin disorders and skin cancer may occur independently of an elective rhinoplasty procedure.

_____ **ALLERGIC REACTIONS**

Initial here Skin allergies to tape, suture material, and topical preparations can occur. Systemic allergic reactions, which are more serious, may occur in response to drugs used during surgery and prescription medicines taken afterward. Allergic reactions may require additional treatment.

_____ **DELAYED HEALING**

Initial here Wound disruption or delayed wound healing is possible. Some areas of the face may not heal normally or may take a long time to heal. If so, further treatment or surgery may be possible to improve the affected tissue.

_____ **LONG-TERM EFFECTS**

Initial here Subsequent alterations in nasal appearance may occur as a result of aging, sun exposure, or other conditions that are not related to the rhinoplasty surgery. In these circumstances, future surgery or other treatments may be possible.

_____ **NASAL SEPTAL PERFORATION**

Initial here There is the possibility that nasal septal surgery will cause an opening between the two sides of the nose. If a perforation (opening) occurs, additional treatment may be possible.

Continued

_____ **NASAL AIRWAY ALTERATIONS**

Initial here After rhinoplasty, septoplasty, or turbinate reduction procedures, changes may interfere with the ideal passage of air through the nose. If this occurs, additional surgery or treatment may be possible to improve breathing.

_____ **SURGICAL ANESTHESIA**

Initial here Both local anesthesia with an intravenous anesthetic and general anesthesia involve risk. Complications and injuries are possible with all forms of anesthesia and sedation.

_____ **HEALTH INSURANCE**

Initial here Most health insurance companies exclude coverage for surgical operations such as rhinoplasty and any related complications that may occur. Please carefully review your medical health insurance subscriber information to better understand your specific policy.

_____ **FINANCIAL RESPONSIBILITIES**

Initial here The cost of surgery involves several charges for the services provided, including the fees charged by your surgeon (i.e., surgeon's fees); the cost of surgical supplies and the use of the operating room (i.e., facility/hospital charges); and the costs associated with anesthesia (i.e., anesthesiologist's fees). Depending on whether the cost of surgery is covered by your medical insurance plan, you will be responsible for necessary copayments, deductibles, and all other charges that are not covered. Additional costs may occur should complications develop from the surgery. Any secondary surgeries and all charges involved with additional procedures (i.e., surgeon's fees, facility/hospital charges, anesthesiologist's fees) would also be your responsibility.

_____ **DISCLAIMER**

Initial here This consent document is written to communicate information about the proposed nasal surgery as well as to disclose information about risks and alternative forms of treatment. The informed-consent process attempts to define principles of risk disclosure that should generally meet the needs of most patients in most circumstances.

However, this consent document should not be considered all-inclusive with regard to defining other methods of treatment to consider and potential risks encountered. Your surgeon will provide you with additional verbal and written information that is based on all of the facts of your particular case and the current state of medical knowledge.

Consent documents are not intended to define or serve as the standard of medical care. Standards of medical care are determined on the basis of all of the facts involved in an individual case and are subject to change as scientific knowledge and technology advance and practice patterns evolve.

There are many variable factors in addition to the specific risks and potential complications that may influence the long-term results of rhinoplasty. The risks cited are those that are particularly associated with rhinoplasty. The practice of medicine and surgery is not an exact science. Although good results are hoped for, there is no guarantee or warranty expressed or implied with regard to the results that may be obtained.

CONSENT FOR RHINOPLASTY SURGERY

1. I hereby authorize my surgeon, _____, and such assistants as may be selected by my surgeon to perform the following procedure: rhinoplasty.
2. I have received, read, and understand the following information sheets:
   - Rhinoplasty (Reshaping of the Nose) Surgery
   - Book chapter about Rhinoplasty Surgery
   - Consent for Rhinoplasty Surgery
3. I recognize that, during the course of the operation, unforeseen conditions may necessitate different procedures than those listed above. I therefore authorize my surgeon, _____, and my surgeon's assistants or designees to perform such other procedures that are in the exercise of professional judgment necessary and desirable. The authority granted under this paragraph shall include all conditions that require treatment and that are not known to my surgeon at the time that the procedure is begun.
4. I consent to the administration of such anesthetics as are considered necessary or advisable. I understand that all forms of anesthesia involve risk and the possibility of complications, injury, and even death.
5. I acknowledge that no guarantee has been given by anyone with regard to the results that may be obtained from this procedure.
6. I consent to the photographing of me (head and neck region) before, during, and after surgery. These photographs may be used by my surgeon for medical, scientific, or educational purposes now and in the future.
7. For the purposes of advancing medical education, I consent to the admittance of observers into the operating room.
8. I consent to the disposal of any body tissues or medical devices that may be removed.
9. **THE FOLLOWING INFORMATION HAS BEEN EXPLAINED TO ME IN A WAY THAT I UNDERSTAND:**
   - **THE PREVIOUSLY DESCRIBED PROCEDURES TO BE UNDERTAKEN**
   - **ALTERNATIVE PROCEDURES AND METHODS OF TREATMENT THAT I HAVE DECIDED AGAINST**
   - **THE SPECIFIC RISKS AND POTENTIAL COMPLICATIONS OF THE PROCEDURES THAT I PLAN TO UNDERGO**

I CONSENT TO THE PROCEDURES AND THE ABOVE LISTED ITEMS (1 THROUGH 9). I AM SATISFIED WITH THE EXPLANATION GIVEN TO ME.

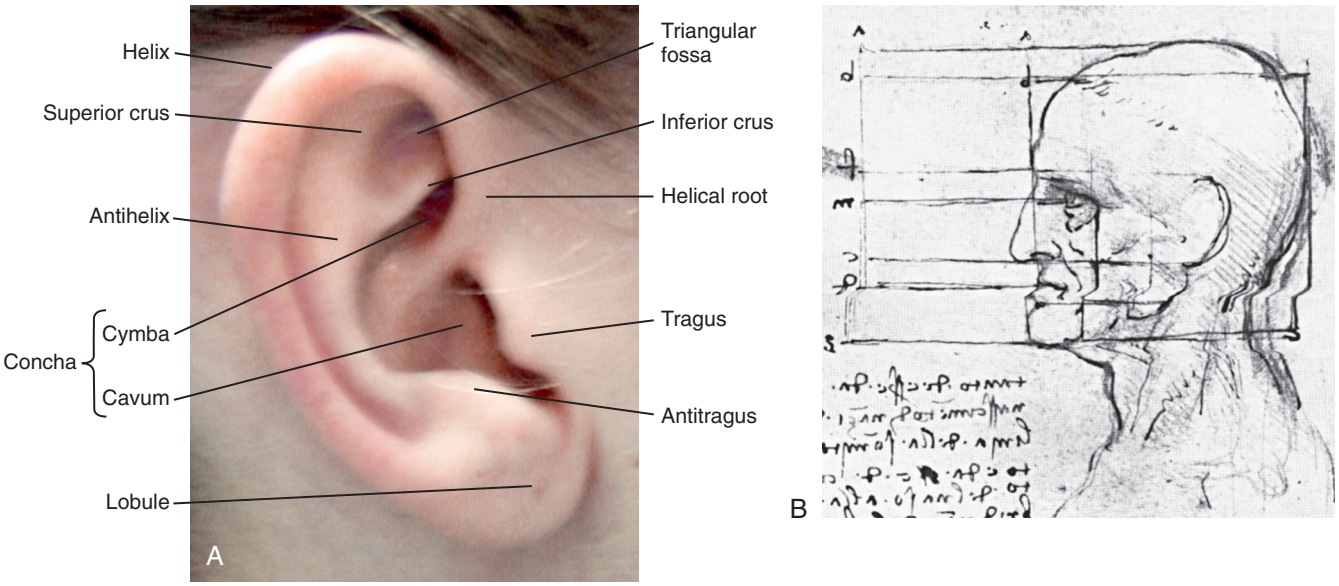
- Otoplasty for Prominent Ears: Step-by-Step Approach
- Assessment of Results
- Complications and Suboptimal Aesthetic Results
- Non-Surgical Correction of Prominent Ears in the Newborn
- Conclusions
- Patient Education Materials

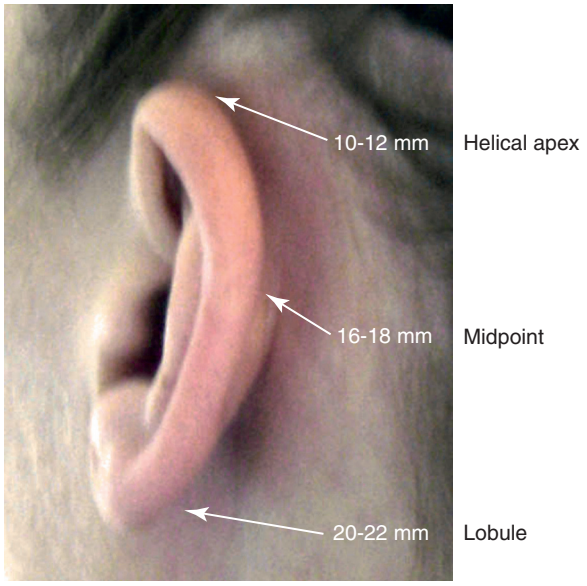
Aside from the excision of auricular tags and the repair of traumatically clefted ear lobes, the *prominent ear* is the most commonly treated external ear deformity. Approximately 5% of the Caucasian population has protruding ears, thereby making this the most frequent congenital anomaly of the external ear. *Otoplasty* is a common aesthetic operation that is carried out among children and adolescents to address this issue. There is a wide variation with regard to what is considered normal for ear size, prominence, and shape (Fig. 39-1). An "outstanding" ear is said to be present when the distance of the helical rim from the temporomastoid surface of the skull is excessive. As a general rule, a measurement of more than 16 to 21 mm is said to result in a prominent ear (Fig. 39-2). The average ear is 6.5 cm long and 3.5 cm wide, but significant variations are considered acceptable. After the completion of normal ear growth and with ongoing age, the external ear changes in that the elongation of the soft tissue covering and the earlobe is to be expected. Provided that the ear has a morphology that is in balance with the other facial features and that there is reasonable symmetry from one ear to the other, these variations are considered to be in an acceptable aesthetic range. However, when ear shape, size, and proportion are perceived as distracting to the casual observer at conversational distance, the ears may become a source of ridicule and personal anguish. Affected children are frequently stigmatized by their peers and commonly ask their parents if a solution for their visible abnormal ear shape can be found. In these circumstances, the surgical correction of the prominent ear is likely to have a beneficial effect on the person's self-esteem and body image.

A *failure of scaphal folding* (i.e., limited antihelical fold) as well as *conchal hypertrophy* (i.e., increased depth of the conchal wall), *prominent lobules* (i.e., protruding ear lobes); and *anterolateral rotation of the concha* (i.e., cupping of the ear) frequently create prominence of the external ear.[5,13,14,30,52,57,67] Noticeable ear protrusion often results from a combination of these deformities. An accurate assessment of the ear dysmorphology is essential to the achievement of an unobtrusive look through surgery. Adjusting the scaphal (antihelical) folding with sutures, reducing the conchal wall depth via conchal excision and conchal mastoid sutures, and performing lobe set-back with sutures and excision are typical components of the surgical correction that is undertaken to achieve a favorable result.[3,4,6,11,26,50,55,60,70,72]

Overemphasis on the surgical creation of an antihelical fold without paying proper attention to conchal hypertrophy often results in an oversharpened antihelix and a buried helical rim (i.e., "telephone ear"). Some surgeons advocate cartilage-cutting (i.e., scoring) procedures rather than sutures to achieve a preferred antihelical fold.[11] These cartilage-scoring techniques generally require dissection of the soft tissues off of the anterior surface of the cartilage. This can result in hematoma, skin necrosis, and chondritis, which may result in irreversible cartilage or external ear irregularities. Surgical correction of the outstanding ear



• **Figure 39-1 A,** The topographic anatomy of the external ear is shown. Key anatomic landmarks are demonstrated and labeled. **B,** Drawing by Leonard da Vinci that confirms the importance of achieving Euclidian proportions of the external ear within the face.



• **Figure 39-2** Ear protrusion is measured as the distance of the helical rim from the cranium; it is measured in millimeters. The specific locations where measurements are taken include the helical apex, the midpoint, and the lobe.

should in general be uncomplicated and result in reliable, long-lasting, favorable aesthetics with minimal downtime for the patient and minimal chance of relapse.

When considering the ideal timing for external ear surgery, it is important to balance what we know about ear and facial growth, psychosocial development, and the ability of the child to comply with the necessary routines after surgery.[1,20,21,39] The goals of otoplasty for the management of congenitally prominent ears, as outlined by McDowell, remain universal despite a multitude of etiologies and suggested surgical techniques.[42] According to McDowell, the surgical goals should include the following:

1. Correcting ear protrusion, by addressing the over prominent helix and antihelix
2. Achieving a smooth antihelical fold without a "sharp" crease
3. Limiting any disturbance to the postauricular sulcus
4. Avoiding a "plastered down" appearance of the ear

Historic Perspective

Dieffenbach is credited with reporting the first otoplasty in the medical literature in 1845.[15] This was performed to reconstruct a traumatically deformed ear. The ear surgery consisted of excising skin from the postauricular sulcus and suturing the conchal cartilage to the mastoid periosteum (i.e., conchal–mastoid suturing). In 1881, Ely was the first surgeon to report a procedure for the aesthetic correction of a congenitally prominent ear.[19] He resected both the skin and the conchal cartilage, but he did so as a two-stage procedure (i.e., one ear at a time).[56] Moristin further developed these skin-excision and cartilage-resection otoplasty techniques.[44] In 1910, Luckett realized that a prominent ear frequently resulted from the congenital failure to form an antihelical fold.[38] He was the first to describe setting the ear back via the removal of postauricular skin and by simultaneously completing an incision through the length of the ear cartilage in an attempt to create the deficient antihelical fold; he also placed sutures to hold the new fold in place. In 1960, Stenstrom used the known principles of cartilage biology as described by Gibson and Davis in 1958 to propose the scoring and abrading the anterior cartilage surface to weaken it and thereby create an antihelical

fold.[61,62,25] In 1963, Mustarde introduced the placement of mattress sutures in the posterior cartilage surface of the ear as a technique for the creation of a new antihelical fold.[46-48]

In 1967, Kaye combined the anterior scoring technique of Stenstrom and the posterior suture placement technique of Mustarde to limit the relapse that surgeons complained about when using either technique alone; he also advocated the use of nonresorbable suture.[32] In 1968, Furnas reintroduced the technique of conchal–mastoid suturing to set back the prominent conchal bowl.[22-24] He also advocated cleaning out the soft tissue in the postauricular groove (i.e., postauricular muscle and fibrofatty tissue) so that the concha could be rotated in a sagittal plane from posterior to anterior (clockwise rotation) before anchoring it to the mastoid fascia (conchal–mastoid sutures) with nonresorbable sutures. In 1969, Webster advocated paying special attention to the prominent earlobe to achieve a successful otoplasty.[69] He noted that the "tail" of the helix could be repositioned with suture to change the lobe's orientation. In 1972, Elliott combined and refined all of the previously described techniques to manage, the deep conchal wall, the limited antihelical fold, and the abnormal earlobe that were frequently seen in the prominent ear.[18] He advocated the use of elliptical partial conchal wall excision when conchal–mastoid suturing alone was felt to be insufficient to correct the ear prominence. He used an anterior incision placed within the "shadow zone" of the conchal margin when conchal resection was required. Bauer advocated the use of the Elliott anterior conchal cartilage excision but preferred to also excise anterior skin to avoid postoperative skin folding or bunching.[4]

Embryology and Anatomy

Embryologically, the ear arises from six hillocks of the first and second branchial arches during the second to fourth month of gestation. Hillocks 1 through 3, from the first arch, form the anteromedial aspects of the auricle (i.e., the tragus, the helical crus, and the helix, respectively). Hillocks 4 through 6, from the second arch, develop into the posterolateral aspects of the ear (i.e., the antihelix and the antitragus, respectively).[34,35] During the third month of gestation, protrusion of the auricle increases. By the end of the sixth month, the helical margin curves, the antihelix forms its folds, and the antihelical crura appear at the superior aspect of the forming external ear. Congenital ear deformities result from the disruption of one or more of the auricular hillocks during embryogenesis. Any deforming forces to the side of the head of the fetus may also alter the shape of the external ear.

The ear is supplied by branches from the superficial temporal artery anteriorly and the posterior auricular and occipital arteries posteriorly. The superficial temporal, posterior auricular, and retromandibular veins provide venous drainage. The lymphatic drainage of the anterior three hillocks is mainly to the anterior triangle of the neck, whereas the posterior three hillocks ultimately drain into the posterior triangle of the neck. Lastly, the ear is supplied by the great auricular nerve on its lower lateral and inferior cranial surfaces, by the lesser occipital nerve on its superior cranial surface, and by the auriculotemporal nerve on its superior lateral surface as well as the anterior superior surface of the external acoustic meatus. The Arnold nerve, which is an auricular branch of the vagus nerve, supplies the posterior inferior external auditory canal and meatus as well as the inferior conchal bowl.[34,35]

The most frequently seen deformity or malformation of the external ear arises from the failure of the antihelix to fold. The conchoscaphal angle widens and results in a flat superior crus, antihelical body, and inferior crus. The helical roll (i.e., the antihelical fold) may be absent altogether or only partially formed, with a wide variation of deformity. Conchal widening (i.e., the presence of a deep conchal bowl) may also occur either as an isolated deformity or in conjunction with antihelical fold deformities. These congenital abnormalities are usually bilateral and often asymmetric, and they frequently demonstrate a familial pattern.

Bauer pointed out that the external ear may be thought of as consisting of a three-tiered cartilaginous framework with tightly adherent skin on the anterior surface and loosely applied skin on the posterior surface.[4] The three tiers of sculpted cartilage form are the helical–lobular complex, the antihelical–antitragal complex, and the conchal complex. Key anatomic (aesthetic) landmarks of the normal ear include the scapha, the concha, the helix, the antihelix, the tragus, and the lobule (see Figs. 39-1 and 39-2).

Timing of Surgery

Auricular deformations are best suited for ear molding correction techniques. Molding therapy is preferably carried out during the first few days of life, as described later in this chapter. In general, the surgical correction of a malformation of the external ear is planned with an appreciation of normal ear maturation. As a result of differing interpretations of ear growth and the effect of an operation on residual growth of the auricle, opinions vary with regard to the preferred timing of definitive external ear reconstruction.

In a study by Farkas, two anthropometric surface measurements, ear width and ear length, were taken directly from the ears of normal subjects with the use of an anthropometric sliding caliper.[20,21] At the age of 1 year, ear width is highly developed in both sexes (mean, 93.5%), and it is mostly completed at the age of 5 years (mean, 97%). The width of the ear reaches its full mature size in boys at the age of 7 years and in girls at the age of 6 years. At 1 year of age, the length of the ear has already attained 75% of its eventual adult size. By 5 years of age, 87% of its eventual development is observed. Ear length achieves its full adult size in 13-year-old boys and 12-year-old girls. Adamson and colleagues reviewed the growth patterns of the external ear and concluded that the ear reaches 85% of its overall adult size by the age of 3 years and that little change in ear width

or the distance of the ear from the scalp occurs after 10 years of age.[1] The authors concluded that, for all practical purposes, the normal ear is almost fully developed by the age of 6 years.

Although children notice differences in each other beginning very early in life, they are rarely self-conscious about differences in ear protrusion before 5 years of age.[39] From this point on, however, social interactions with peers frequently elicit negative comments that can affect self-esteem and body image. The correction of external ear deformities before this age is possible, but the postoperative course may be compromised if the ear bandage is removed early by the uncooperative child or with disruption of the repair by pulling on the ears after the bandage is removed. Consideration is given to setting back the protruding ears as early as 3 years of age, although many children display improved cooperation and parents are more confident in their decision when children are between the ages of 5 and 6 years.

Aesthetic Objectives

It is recognized that there are wide variations with regard to ear proportions, projection, and position among individuals. When feasible, the surgically reconstructed (previously protruding) ear should be of ideal size and shape and have a good relationship with the other facial features and the contralateral ear. Loose guidelines for the assessment of preferred ear shape and position have been summarized by Tolleth.[67]

Ear Axis

A line that passes through the longest dimension of the ear is called its *axis*. In the majority of people, an angle of 20 degrees formed between the axis of the nasal bridge and the axis of the ear is considered the most aesthetically pleasing. The axis of an aesthetically pleasing ear is rarely vertical.

Ear Position

When the head is in the true horizontal (natural head) position, the top of the ear will generally be level with the eyebrow, whereas the bottom of the ear will generally be on a line with the base of the columella of the nose or slightly lower. In the anteroposterior dimension, the ear is roughly positioned one ear length (i.e., 6.5 to 7.5 cm) posterior to the lateral rim of the orbit.

Ear Size

A wide variation exists with regard to what is considered normal ear size in terms of length and width. The length of a "normal" ear varies from 5.5 to 7.5 cm, whereas a normal ear width varies from 3.0 to 4.5 cm. The normal width-to-length ratio is 50% to 65%.

Ear Protrusion

Although the spectrum of protrusion of the helical rim from the scalp varies widely, a measurement of 1.5 to 2.0 cm is aesthetically acceptable.[2]

Patient and family satisfaction should be anticipated if the reconstructed ears are no longer a facial feature that draws attention when viewed at conversational distance by the casual observer. Sharp angles, unnatural contours, overcorrection and "eye-catching" asymmetry from ear to ear are not ideal. In the operating room, the surgeon should view the reconstructed ear from several feet of distance in frontal and profile views and from the rear. From the rear, the helical contour should form a relatively straight line; this will indicate that the antihelical fold (the upper third), the conchal depth (the middle third), and the lobe (the lower third) are in sync. From the front, the helical rim above and the lobe below should be seen to an extent just beyond the antihelix without any cupping of the upper and lower thirds of the ear. In profile, the contours should be gentle and the folds rounded.

Surgical Principles

A reconstructed prominent ear should be reasonably symmetrical with its counterpart and without a sharply angulated antihelical fold. If the upper third of the ear protrudes as a result of an absent or weak antihelical fold, then the fold should be improved (i.e., Mustarde and superior helix–mastoid stitches). If the middle third of the ear is too prominent (i.e., outstanding and away from the side of the head), then the concha must be recessed (i.e., conchal wall excision and conchal–-mastoid stitches) and the antihelical fold improved (i.e., Mustarde stitches). In the lower third of the ear, if the lobule protrudes, the surgeon must resect or reposition the cartilaginous tail, excise the retrolobular skin, or both.

Historically, the creation of an *antihelical fold* was carried out by techniques that involved either scoring or abrasion of the cartilage to control the direction and extent of folding.[16,25,28] Later, suture techniques (i.e., Mustarde sutures) were added to reshape the cartilage. Many surgeons combine these methods. Interestingly, some "cartilage scorers" recommend partial-thickness scoring, whereas others score the full thickness of the cartilage.[11] This author prefers to avoid scoring the cartilaginous surface all together, because this requires separation of the anterior skin from the cartilage surface with increased risk of hematoma, flap necrosis, and visible sharp edges on the anterior (cartilage) surfaces. The careful placement of Mustarde mattress sutures in a gentle curve will form a smooth antihelical fold. The Mustarde sutures are placed along the posterior surface of the cartilage as needed in the upper, middle, and lower thirds to accomplish aesthetic antihelical folding.[46-48]

Conchal hypertrophy is a frequent component of the ear deformity. The correction of this aspect is usually

accomplished through a combination of techniques, including the following: 1) the repositioning of the concha into the surgically "cleaned out" mastoid recess; 2) conchal setback with conchal–mastoid sutures; and 3) conchal reduction through direct elliptical cartilage excision. If the anterior approach is selected for conchal wall resection, an incision (scar) must be placed on the anterior surface, but the folding of redundant skin is limited.[4] If a posterior approach is used, there is a risk that the redundant anterior skin that is left behind may not shrink sufficiently and thus result in a visible fold in the conchal floor. Some surgeons believe that a redundant anterior skin fold may be more noticeable than a "fine" anterior conchal scar. This author prefers to excise conchal cartilage with the use of a posterior approach. The anterior skin is then released from the residual conchal floor cartilage to avoid bunching, as discussed later in this chapter.

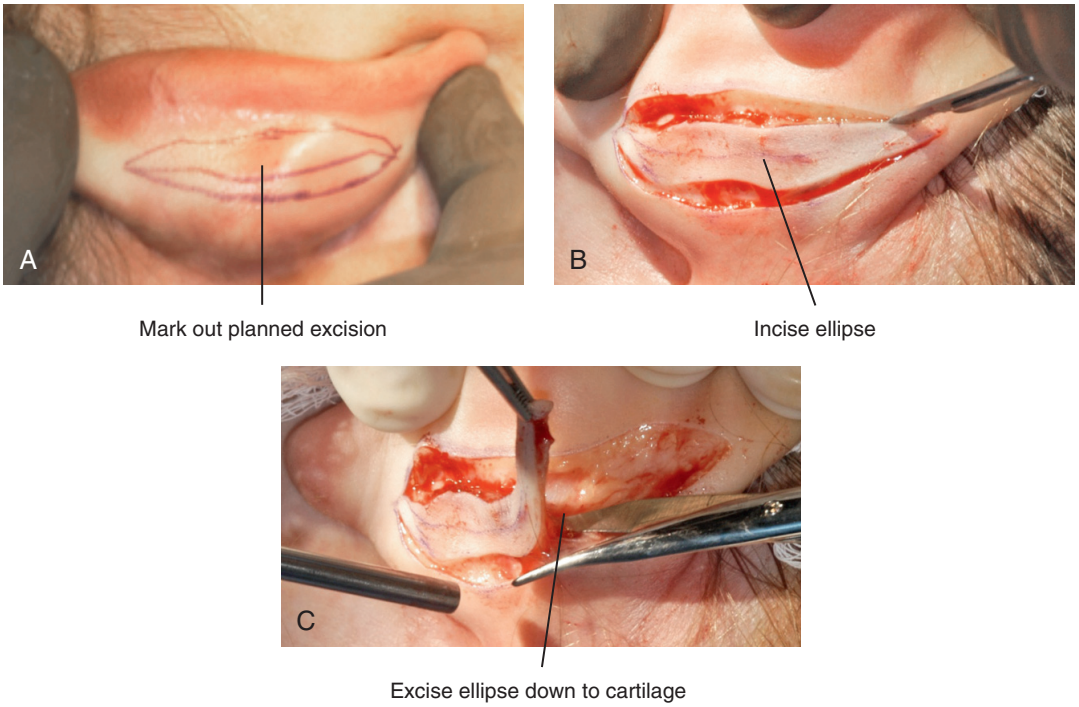
To review, the *ear set-back procedure* will generally require the resection of conchal (wall) cartilage, the cleaning out of excess soft tissues in the retroauricular sulcus, and three rows of deep sutures. These three rows of sutures include the following: 1) Mustarde horizontal mattress sutures to create an antihelical fold; 2) conchal sutures for reconstructing after elliptical (conchal wall) resection; and 3) Furnas-type sutures, including placement in the conchal–mastoid region and the superior helix–mastoid region. Nonresorbable sutures should be used to limit relapse (4-0 Mersilene versus 4-0 clear nylon).

Surgical Technique
(Figs. 39-3 through 39-9)

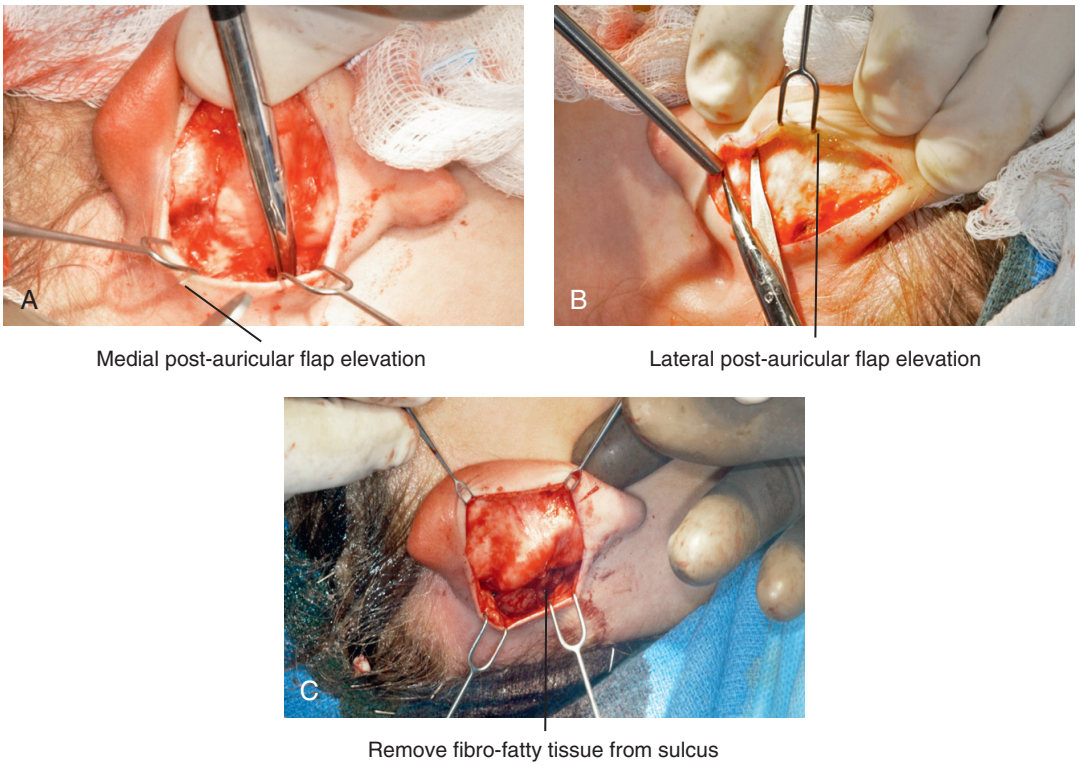
The intraoperative draping of the patient within the sterile field should provide visualization of both ears and the entire forehead, face, and neck as well as the ability to safely turn the patient's head from side to side. An orotracheal tube with a natural curve at the level of the lower lip is used and secured to the skin of the chin with a minimal amount of tape (e.g., an Oral RAE endotracheal tube). Ophthalmic eye ointment and eye protectors (corneal shields) are placed below the eyelids to limit corneal injury and to prevent the need for tape or dressing material on the face. The patient's head is placed on the Mayfield horseshoe head ring in the neutral neck position. The Mayfield provides stability and adequate exposure and allows for the turning of the head without disrupting the surgical field. The majority of the hair is wrapped in a sterile towel, and prophylactic intravenous antibiotics are given. A mouth pack is placed to limit saliva contamination of the surgical field.

The ears are marked on the anterior surface for the creation of a new or improved antihelical fold and on the posterior surface for an elliptical skin excision. Lidocaine (Xylocaine) 1% with 1:100,000 epinephrine is injected into the postauricular skin fold.

The postauricular incisions (i.e., elliptical skin excision) are completed with a scalpel (see Fig. 39-3). All soft tissue



• **Figure 39-3** Intraoperative views of postauricular skin incisions and excision as part of otoplasty. **A,** The location of the postauricular elliptical skin excision is demonstrated. The planned long axis of the ear excision extends from the superior helical rim to the earlobe. **B,** With the use of a knife (No. 15 blade), the full thickness of the skin ellipse is incised. **C,** With the use of blunt-tip Stevens scissors, the full thickness of the skin ellipse is removed, down to the surface of the cartilage.



• **Figure 39-4** Intraoperative views of postauricular flap elevation and then subcutaneous tissue excision as part of otoplasty. **A,** Elevation of the medial postauricular flap is completed down to the mastoid fascia. **B,** Elevation of the lateral postauricular flap is extended to the outer edge of the helical rim. The flaps are also elevated inferiorly to the tail of the helix and superiorly to the upper aspect of helix. **C,** All soft tissue is cleaned out in the sulcus down to mastoid fascia (i.e., muscle and fibrofatty tissue).

down to the posterior surface of the cartilage is removed. The postauricular medial and lateral skin flaps are elevated (see Fig. 39-4). The resection and removal of postauricular muscle and fibrofatty tissue that is between the conchal cartilage and the mastoid fascia is completed. This allows the concha to rest in a deep pocket so that the bending of the cartilage over a soft-tissue mound does not occur when tying conchal–mastoid sutures (Fig. 39-6A).

When scaphal folding is needed to improve the antihelical fold, the placement of postauricular horizontal mattress (Mustarde-type) sutures is carried out (see Figs. 39-5 and 39-6). Before the creation of the improved antihelical fold, the posterior cartilaginous surface is cleaned of all soft tissue. The Mustarde sutures are placed in a radial fashion to form a curved scaphal fold that extends from the superior crus down to the lobule. Antihelical reconstruction usually requires three to five Mustarde sutures to achieve a smooth roll. Each suture is tested for its effectiveness after it is placed, but none are tied until all are in position. If the position of the superior helix remains protruded, one or two additional superior helix–mastoid sutures can be placed to further accomplish the ear set-back.

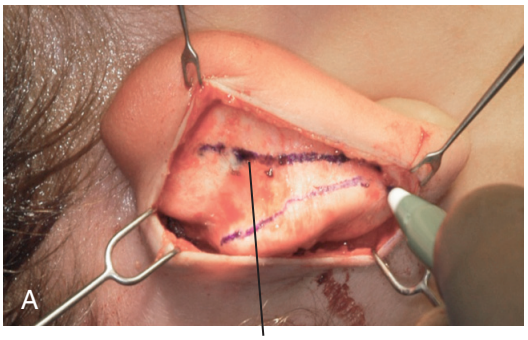
A conchal set-back with sutures (conchal–mastoid sutures) is useful but generally inadequate for the management of even moderate degrees of conchal hypertrophy. Partial conchal wall resection is generally indicated (see Figs. 39-7 through 39-9). This author prefers to complete the resection through a posterior approach. An ellipse of the conchal wall that extends superiorly and inferiorly is excised to allow the bowl to reposition itself without a cartilaginous "dog ear" (i.e., puckering). If only minor degrees of conchal prominence exist, management just with the placement of conchal–mastoid sutures may be possible.

The position of the lobule can be further managed by the setting back of the tail of the helix. The helical tail is exposed on its posterior surface. The tail is sutured back to the concha or the mastoid fascia. Each placed suture is tested to determine if the desired position of the lobule will be achieved. In some patients, it is useful to excise cartilage at the lobule to achieve adequate positioning. In others, the excision of a postauricular wedge of skin is helpful.

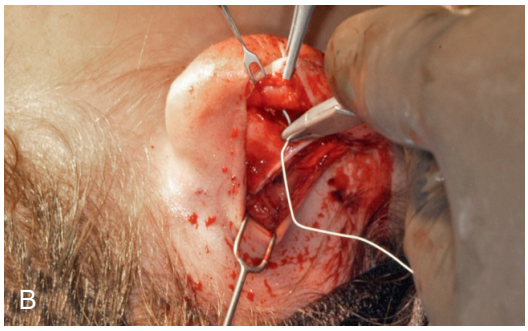
Otoplasty for Prominent Ears: Step-by-Step Approach

Positioning on the Operating Room Table

- Place the patient supine on the operating table with his or her head resting on the Mayfield horseshoe. The neck should be in the neutral position.



Mark out anti-helical fold



Placement of (3-5) horizontal mattress "Mustarde" sutures (4-0 merseline)

Confirm new anti-helical fold prior to tying down

• **Figure 39-5** Intraoperative views of the creation or deepening of the preferred antihelical fold as part of the otoplasty. **A,** The preferred antihelical fold is located and marked on the posterior surface of cartilage with a surgical pen or methylene blue. **B,** The new antihelical fold is created or deepened by placing three to five carefully located horizontal mattress (Mustarde-type) sutures. The sutures are placed in a natural curve like the spokes of a wheel. Each placed Mustarde suture is tested for effectiveness with a single throw, after which it is loosened. **C,** After all sutures have been placed and tested, each will be carefully tied and confirmed for the preferred aesthetic effect. Note that the conchal wall excision is completed prior to placement of Mustarde stitches. Only after all of the Mustarde stitches have been secured, are the edges of the conchal walls (after elliptical excision) approximated with the use of interrupted sutures.

General Anesthesia Intubation

- Place the orotracheal (Oral RAE) tub.
- Tape the endotracheal tube to the chin.
- Be sure that the anesthesia ventilation tubing extends over the anterior chest in the midline and then goes off to the side.

Corneal Protection

- Place the ophthalmic eye ointment.
- Place the corneal shields deep to the eyelids.

Medications

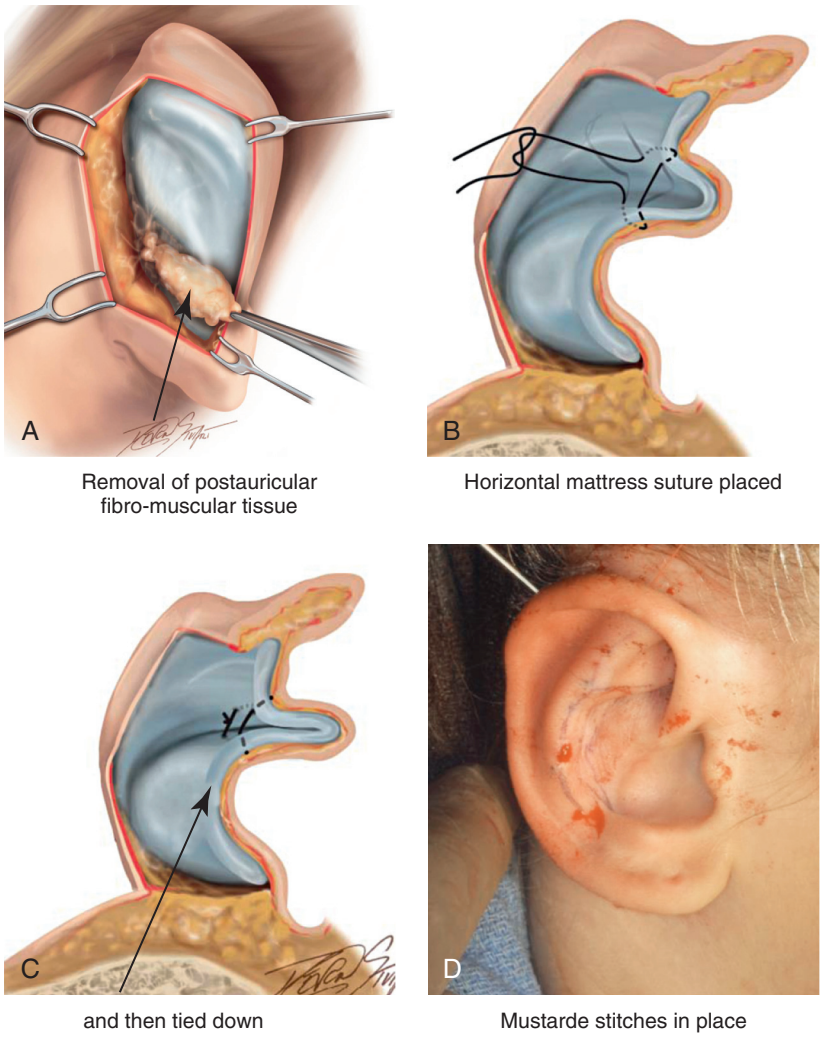
- Administer intravenous antibiotics (Cefazolin 17 mg/kg/dose, max: 1 gm).
- Administer steroids via an intravenous bolus (Dexamethasone 0.5 mg/kg/dose, max: 8 mg).

Preparation and Draping

- If the patient has long hair, tie it in a ponytail; this will keep the hair out of the surgical field.
- Prep the patient's entire scalp, forehead, external ears, face, and neck.
- Use Betadine solution (do not use soap, alcohol, Hibiclens, and so on) to avoid irritation of the mucous membranes and the corneas of the eyes.
- Drape the patient, leaving the anterior scalp, forehead, external ears, face, and neck exposed in the operative field.

Surgical Markings

- Before preparation, use a surgical pen to locate and mark the preferred location of the antihelical fold on the anterior aspect of the ear, including the superior and inferior crus.



• **Figure 39-6** Illustrations and patient example of the surgical correction of an antihelical fold. **A,** Illustration that demonstrates the removal of redundant fibromuscular tissue from the postauricular fold. **B,** Illustration that demonstrates the placement of a Mustarde stitch before tie down (cross section view). **C,** Illustration of a tied-down Mustarde stitch (cross section view). **D,** Intraoperative view of the anterior surface of the ear just after the placement of five Mustarde stitches that were used to create the preferred antihelical fold.

- Before preparation, use a surgical pen to locate and mark the postauricular elliptical skin excision. Center the ellipse at the long axis of the ear from the superior helical rim to the earlobe. Stop the ellipse approximately 1 cm short of the superior and inferior margins of ear.

Local Anesthesia

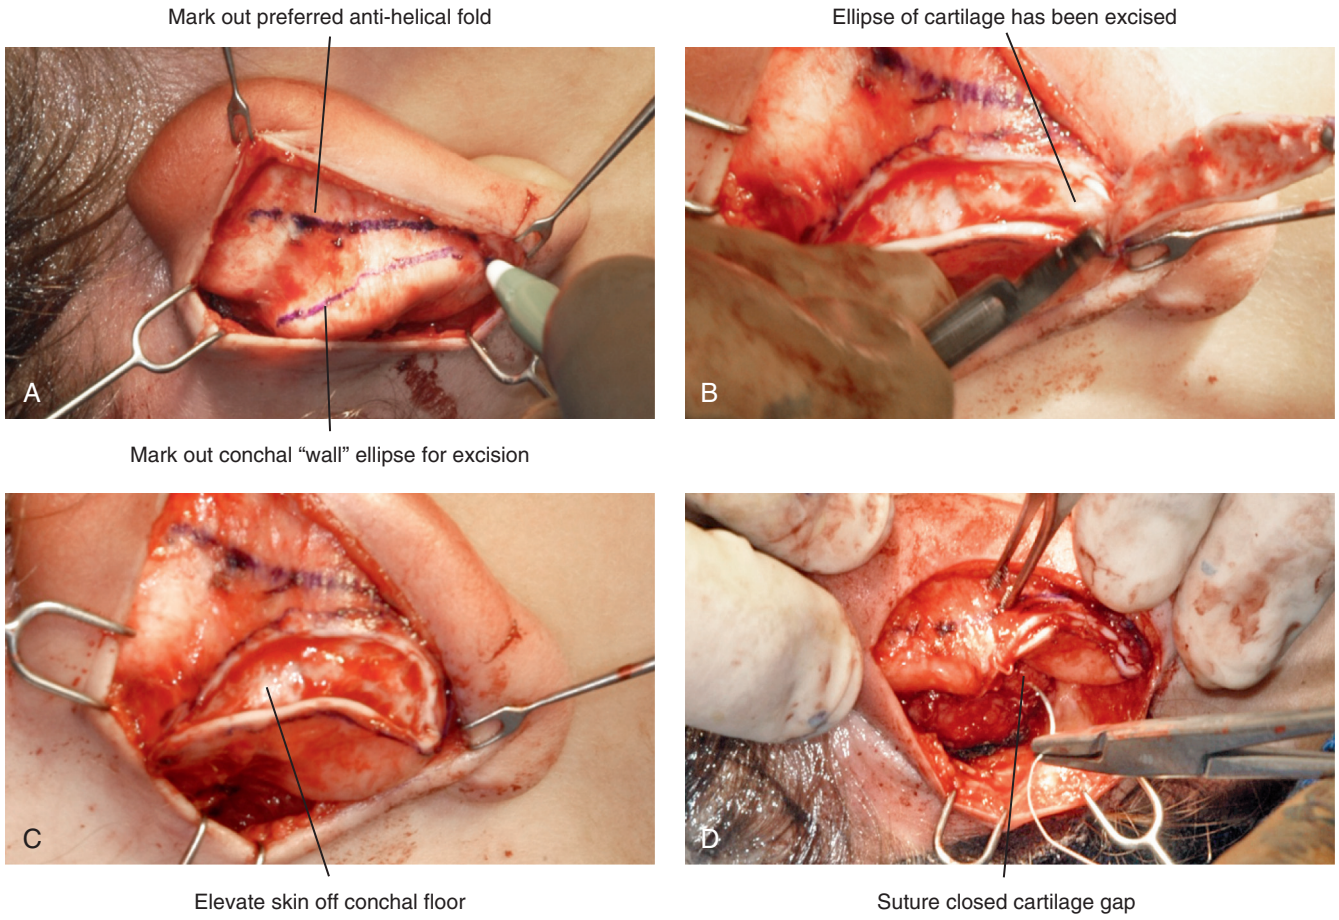
- Inject Xylocaine (1% with 1:100,000 epinephrine) into the postauricular sulcus above the mastoid fascia and superficial to the ear cartilage.

Postauricular Skin Excision (see Fig. 39-3)

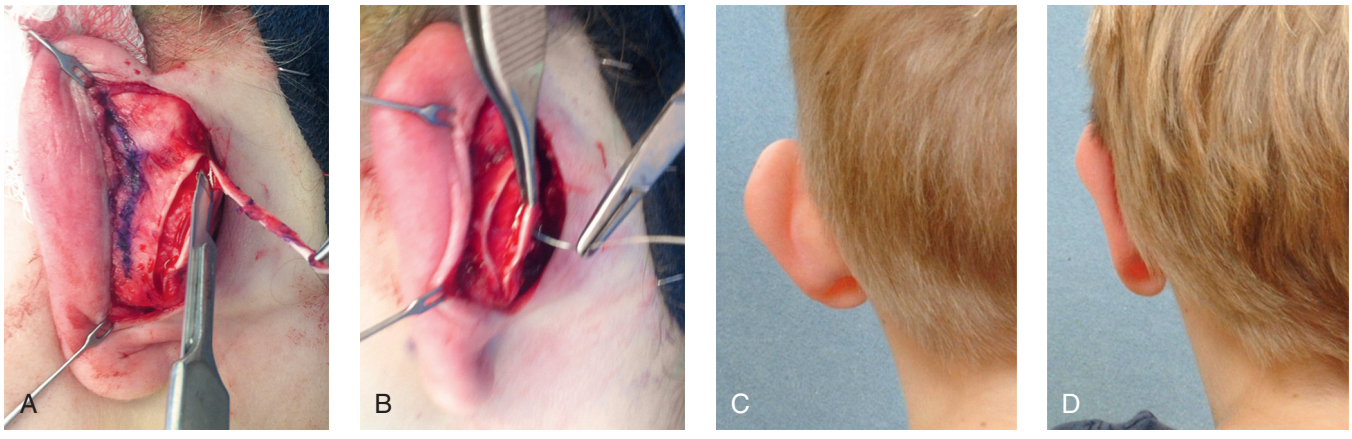
- With a knife (no. 15 blade), incise the full thickness of the skin ellipse.
- With blunt-tipped Stevens scissors, remove the full thickness of the skin ellipse down to the surface of the cartilage.

Elevation of the Postauricular Flaps (see Fig. 39-4)

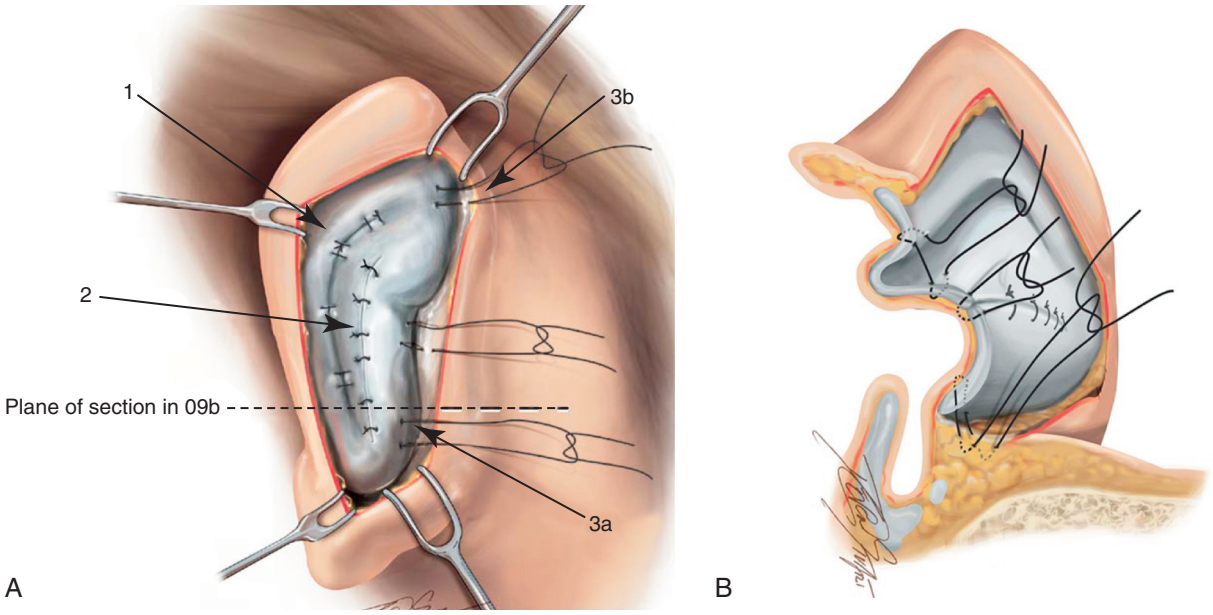
- Elevate the lateral postauricular skin flap near the outer edge of the helical rim.
- Elevate the medial postauricular skin flap down to the mastoid fascia.
- Clean out all soft tissue (i.e., muscle and fibrofatty tissue) in the sulcus down to the mastoid fascia.
- Confirm the adequate elevation of the flaps inferiorly (to the tail of the helix) for later control of the earlobe position and superiorly (the upper aspect of the helix)



• **Figure 39-7** Intraoperative views of conchal wall resection and reconstruction as part of otoplasty. **A,** The preferred antihelical fold is located on the posterior surface of the cartilage and marked with a surgical pen or methylene blue. In addition, the long axis for the planned elliptical excision of the conchal wall is located and marked on the posterior surface of the cartilage. **B,** The full thickness of the conchal wall ellipse for excision is incised through the cartilage with a knife (No. 15 blade) but without perforation through the anterior skin. The cartilage is then removed with the use of a Cottle elevator and Stevens scissors. This image was created after the ellipse of cartilage had been excised. **C,** Next, the anterior ear skin is elevated off of the residual conchal floor toward the ear canal. This is accomplished to limit bunching of the skin during the healing phase after the conchal wall edges are reapproximated with suture. **D,** The edges of the cut conchal wall are sutured together to limit overlap during healing. Note that it is best to suture the conchal edges together only after the Mustarde sutures are placed and tied.



• **Figure 39-8** Illustration and patient example of deep conchal bowl correction. **A,** Illustration of the postauricular approach for access and then for the excision of the ellipse of the conchal wall. **B,** Intraoperative view after the elliptical excision of the conchal wall to "set-back" the ear. The anterior soft tissues of the ear remain intact. **C** and **D,** Clinical example of a child with a deep conchal bowl before and after surgical correction.



• **Figure 39-9** Illustrations of a postauricular approach to the management of a prominent ear. Frequently, three rows of sutures are required for successful ear set-back. **A,** The illustration demonstrates the three rows of sutures being placed, but they are not yet tied down (cross section view). **B,** Illustration of the three rows of sutures (post auricular view) after they are tied down. The three rows of sutures include the following: 1) Mustarde (scaphoconchal) sutures; 2) conchal wall resection and then suture reconstruction of the cartilage defect; and 3) conchal–mastoid and superior helix–mastoid sutures.

for later control of the position of the upper third of the helix.

Marking of the New Antihelical Fold on the Posterior Surface of the Cartilage

- With the use of a 27-gauge needle (i.e., a tuberculin syringe filled with methylene blue), puncture through the anterior surface of the skin along the previously marked location of the new antihelical fold.
- Visualize the needle on the posterior surface of the cartilage, and use a surgical pen or methylene blue to mark the location of the new fold along the full length from the superior crus to the tail. This will allow for the accurate placement of the Mustarde-type sutures.
- Mustarde sutures are not placed until after conchal wall resection is complete.

Conchal Wall Resection for Set-Back (see Figs. 39-7 and 39-8)

- The planned elliptical excision of the conchal wall (superior to inferior) is marked out with a surgical pen or methylene blue on the posterior surface of the cartilage.
- The conchal excision should include a portion of the conchal wall. The full thickness of the ellipse of concha for excision is incised with a scalpel (no. 15 blade) but without perforation through the anterior skin.
- With the use of a Cottle elevator, the incised ellipse of cartilage is freed from the anterior ear skin and then removed.
- The anterior ear skin is further elevated off of the residual concha floor toward the ear canal. This will limit bunching of the skin during the healing phase after the conchal wall edges are reapproximated with suture.
- The edges of the cut conchal wall will be sutured together with 4-0 Vicryl to limit overlap. Wait to suture the edges together until the Mustarde sutures are placed and tied.

Deepening or Creation of the Antihelical Fold (see Figs. 39-5 and 39-6)

- The new antihelical fold is created or deepened by placing three to five carefully located horizontal mattress (Mustarde-type) sutures. The sutures are placed in a natural curve like the spokes of a wheel.
- Experience has taught that cartilage scoring is not necessary and can cause complications (e.g., hematoma, skin flap necrosis, sharp edges).
- Each placed Mustarde suture is tested for effectiveness with a single throw, after which it is loosed.
- When all sutures have been placed and tested, each is carefully tied and confirmed for the preferred aesthetic effect.
- Experience has taught that use of non-resorbable suture (4-0 Mersilene or 4-0 clear nylon) is useful to limit or

prevent late cartilage relapse with the loss of the antihelical fold.

Conchal Wall Resection for Set-Back (Continued)

- Now that the Mustarde sutures have been secured, the cut edges of the conchal wall are approximated with the use of interrupted 4-0 Vicryl sutures to limit overlap.

Placement of Conchal–Mastoid Sutures to Further the Set-Back of the Middle Third of the Ear (see Fig. 39-9)

- Conchal–mastoid sutures are placed as needed only after the conchal wall is resected and reconstructed with sutures and the Mustarde sutures have been placed. The conchal–mastoid sutures should be made of a non-resorbable material (4-0 Mersilene or 4-0 clear nylon) to limit cartilage relapse. They are placed to establish the preferred clockwise rotation of the ear and to further set back the middle concha, as needed.
- If more than one conchal–mastoid suture is required, each is placed and tested with a single throw and then loosened.
- When all of the conchal–mastoid sutures have been placed and tested, each one is tied to confirm the preferred aesthetic effect.

Placement of Superior Helix–Mastoid Sutures to Further the Set-Back of the Upper Third of the Ear

- The superior helical rim may remain "outstanding" more than is preferred even after the placement of Mustarde sutures. A superior helical–mastoid suture (4-0 Mersilene or 4-0 clear nylon) is often useful to further improve the aesthetic result. The combination of these surgical maneuvers will limit a sharp edge in the antihelical fold that may otherwise occur as a result of the overtightening of the Mustarde sutures.

Set-Back of the Earlobe (Lower Third of Ear)

- Excision of the postauricular skin and the subcutaneous tissue of the lobe is sometimes helpful to set back the lower third of the ear.
- The placement of a tail of helix–mastoid or tail of helix–conchal base suture with the use of non-resorbable material (4-0 Mersilene or 4-0 clear nylon) is sometimes helpful to control the lobe position.

Skin Closure

- The placement of several interrupted sutures and then a running and locking suture of resorbable material (5-0 chromic) is used for skin closure. This prevents the need for postoperative suture removal.

Placement of Dressing (Fig. 39-10)

- A thick coat of antibiotic ointment is placed in the postauricular fold and over the anterior ear skin surface.
- A sheet of gauze (Xeroform) is placed in the postauricular groove and also along the anterior ear surface.
- Two or three pieces of dry fluff gauze are placed over the anterior skin surface of each ear.
- A gauze roll (Kerlix) is used as a wrap to apply gentle pressure and to hold the gauze fluffs in place. The Kerlix wrap is also secured across the anterior neck to prevent the head dressing from loosening.
- An Ace wrap is then loosely placed as an outer layer of the head and ear dressing.
- The whole dressing is removed 5 days later.

Postoperative Care

- After the ear dressing is removed, the patient is encouraged to shower and shampoo the hair and to wash the external ears, face, and neck one or two times daily. (Overly hot water should be avoided, because the ears will have diminished sensation.)
- The ears are dabbed dry after washing. (Excess rubbing of the ears should be avoided.)
- Ear protection is used when sleeping for 2 to 3 months to prevent accidental anterior folding of the external ears. A skier's ear warmer or a tennis sweatband may be used for this purpose.
- No vigorous sports activities are allowed for 4 to 6 weeks.
- No strong sun (ultraviolet) exposure to the ears is allowed for approximately 3 months.
- When the patient has returned to more regular physical or sports activities after 4 to 6 weeks, additional precautions are encouraged, depending on type of sport activity (e.g., wrestling, basketball), during the initial 3 months after surgery.

Assessment of Results

Although prominent ears do not have any physiologic disadvantages, they play an important role in social life. Prominent ears often provoke teasing by others, especially by children; they can lead to emotional stress with a decline in the patient's health-related quality of life; they may negatively affect school or job performance; and they may result in social avoidance and a loss of self-confidence (Figs. 39-11 through Fig. 39-27). Today, health-related quality of life is considered by many to be the most important parameter for the evaluation of aesthetic procedures such as the correction of protruding ears.[7,64]

In a recent study by Braun and colleagues, a consecutive series of patients (N = 84) who underwent otoplasty (suture technique) were given a health-related quality-of-life survey.[6]

The survey used was either the Glasgow Children's Benefit Inventory (N = 41; 73.8% of study group) or the Glasgow Benefit Inventory (N = 21; 33.9% of study group). Both of these quality-of-life surveys have been validated for measuring the effect of plastic (aesthetic) operations on health-related quality of life. Sixty-two patients (73.8%) returned a valid questionnaire for analysis. For the study group, the main reasons for carrying out the ear set-back operations as reported by the patient and the family included teasing (42.6%); aesthetic impairment (39.3%); and reduced self-confidence (23%). The results of the study indicate that 100% of the adults were satisfied with their aesthetic results and that 90.5% would again decide in favor of the operation. Ninety-five percent of the parents of the children and 95.1% of the children themselves were satisfied with the aesthetic results. Ninety-seven percent of the parents and 92.7% of the children then also stated that they would again decide in favor of the operation. The authors also speculated that an individual's reluctance to participate in certain social activities, if caused by reduced self-confidence as a result of the protruding ears, was more likely to remain constant with increased age. In other words, adults that had lived through the social ridicule of prominent ears for many years were more likely to retain reduced self-confidence even after successful ear set-back.

Complications and Suboptimal Aesthetic Results

Although the majority of patients state that they are satisfied with their otoplasty results and say that they would undergo such procedures again, complications and suboptimal results will always occur in a minority of cases.[10,17,31,37,53,54,63]

Pinching of the External Auditory Canal

Conchal-mastoid sutures that are placed too far forward on the mastoid or too far back on the concha may exaggerate the conchal rotation. In theory, the created angular edge of the auditory canal may diminish the diameter of the canal. This problem can be minimized by managing conchal hypertrophy with elliptical excision rather than with the overaggressive use of conchal–mastoid sutures.

Inadequate Management of Conchal Hypertrophy

Many patients who are dissatisfied with the aesthetic results of an otoplasty demonstrate residual conchal hypertrophy that was missed, ignored, or undertreated. When conchal hypertrophy is part of the deformity, it should be adequately addressed. This author prefers the elliptical resection of the outstanding conchal wall in most cases. The placement of conchal–mastoid sutures alone is often inadequate and results in either immediate or late relapse.

A "Too-Sharp" Antihelical Fold

An unnaturally sharp antihelical fold may be created as a result of overaggressive scoring of the cartilage or overtightening of the Mustarde sutures in the presence of undercorrected conchal hypertrophy.

• **Figure 39-21** A 9-year-old girl with a unilateral (right-side) prominent ear that is characterized by conchal hypertrophy and a lack of scaphal folding. She underwent a unilateral otoplasty. The ear cartilage was extremely thin and flexible. She underwent conchal rotation and set-back (conchal–mastoid sutures) and the creation of antihelical folding (Mustarde sutures). **A,** Frontal views before and after reconstruction. **B,** Right profile views before and after reconstruction.

Excessively Prominent Earlobe

After the traditional surgical management of the antihelical fold, one area of the prominent ear that may require additional attention is the earlobe. At times, this problem can be addressed with additional posterior skin excision. If the lobe still projects forward and laterally, consideration should be given to the removal of cartilage deep to the antitragus (cavum conchalis) to allow the lobe of the ear to be aesthetically retropositioned. This may be carried out as an extension of the conchal bowl excision. For others, the prominent earlobe is managed with suturing of the tail of the helix to either the mastoid fascia or the conchal base.

Failure (Relapse) of Scaphal (Upper Helix) Folding

In some patients, the created antihelical fold will open (relapse) with recurrence of the prominent ear appearance. This may occur for one of several reasons. If a Mustarde stitch becomes inflamed or infected, it may loosen, which results in the unfolding of the helix. In other situations, an

• **Figure 39-22** A 9-year-old boy with malformed and asymmetric external ears who underwent reconstruction. His procedures included asymmetric elliptical conchal wall resection (posterior approach); conchal rotation and stabilization (conchal–mastoid and superior helix–mastoid sutures); the creation of the antihelical fold (Mustarde sutures); and earlobe set-back (soft-tissue sutures). **A,** Frontal views before and after reconstruction. **B,** Profile views before and after reconstruction.

uncooperative child may pull on the ears, thereby causing shearing of the sutures with a recurrence of ear prominence. For others, the sutures may not have a sufficient "bite" into the cartilage and thus not withstand the recoil forces. In this author's experience, the use of non-resorbable (4-0 Mersilene or 4-0 clear nylon) suture is an important aspect for the limiting of relapse tendency.

In some patients, despite the placement of Mustarde stitches, the upper helix still protrudes. If residual protrusion of the upper third of the helix is observed early after surgery, it is most likely an intraoperative technical error rather than cartilage relapse. To prevent this problem during operation, rather than overtightening the Mustarde stitches, it is best to place a superior helix–mastoid suture.

Residual Ear Asymmetry

When managing unilateral or bilateral ear prominence, the preoperative assessment should clarify any baseline asymmetry of the auricles. Each ear should be treated indepen-

• **Figure 39-25** A middle-aged man with a lifelong history of prominent ears that are characterized by limited antihelical folding and a degree of conchal hypertrophy. He underwent conchal wall resection (posterior approach); conchal stabilization (conchal–mastoid sutures); and deepening of the scaphal folding (Mustarde sutures). **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Profile views before and after reconstruction.

• **Figure 39-26** A high school student who was born with hemifacial microsomia underwent simultaneous jaw and external ear reconstruction (see Fig. 28-15). Although the ears are asymmetric in morphology and position, they were simply set back. The left ear underwent both conchal wall resection (posterior approach) and improvement of the scaphal fold (Mustarde stitches). The right ear required improvement of the scaphal fold (Mustarde stitches) and the placement of superior helix–mastoid sutures. **A,** Frontal views in repose before and after reconstruction. **B,** Frontal views with smile before and after reconstruction.

• **Figure 39-26, cont'd C,** Left oblique facial views before and after reconstruction. **D,** Right oblique facial views before and after reconstruction.

• **Figure 39-27** A 5-year-old child with Treacher Collins syndrome underwent zygomatic–orbital reconstruction and bilateral external otoplasty (see Fig. 27-11). The external ear procedures included elliptical conchal wall resection (posterior approach); conchal rotation and stabilization (conchal–mastoid suture); and the improvement of the antihelical folds (Mustarde sutures). **A,** Frontal views before and after reconstruction. **B,** Oblique facial views before and after reconstruction. **C,** Worm's-eye views before and after reconstruction.

dently but with consideration of overall facial symmetry and balance. Ear asymmetry is easily glossed over preoperatively; however, when scrutinizing the ears after surgery, even minor asymmetry may take on greater importance. Good-quality facial photographs before and soon after surgery should be reviewed with the patient and the family to avoid misunderstandings.

Postsurgical "Telephone Ear" Appearance

The "telephone ear" deformity is caused by overaggressive set-back (antihelical folding) in the middle third of the helical rim in combination with the undercorrection of the earlobe and the superior third of the helix. This generally occurs when conchal hypertrophy has not been appropriately addressed.

Postsurgical "Flat Ear" Appearance

The postsurgical "plastered back" appearance of the external ears occurs when the antihelical fold is sharp and excessive in combination with the overreduction of the conchal wall.

Infection of the Cartilage (Chondritis)

Infection after ear surgery is not common. Chondritis is more likely after aggressive anterior flap elevation and cartilage scoring, especially when contamination occurs.

Necrosis with Loss of Skin

Necrosis is more likely to occur with wide anterior flap undermining when inadequate attention has been given to circulation requirements. It may also occur as a result of an overly tight ear dressing or bandage, a hematoma beneath the dressing, or a combination of these factors.

Abnormal Scar Formation

Hypertrophic scarring can occur at any wound closure. It is more likely in the presence of infection or poor circulation or with excessive scratching or rubbing by the patient postoperatively. Keloid formation can occur and may be differentiated from hypertrophic scarring by a positive personal or family history and scar enlargement that extends outside of the operative site. Current options for the management of a keloid scar are often suboptimal but may include intralesional steroid injections, cutaneous irradiation, or re-excision.

Suture Granuloma ("Stitch Abscess")

Occasionally a buried suture will develop a granulomatous reaction around it. The offending suture will either spontaneously exfoliate or require surgical removal. This seems to be more frequent with Mersilene suture material. Removal under local anesthesia can be difficult in a child.

Non-Surgical Correction of Prominent Ears in the Newborn

Although the idea of "binding" the external ears in an attempt to correct abnormalities is not a new one, Matsuo and colleagues can be credited with examining the efficacy of doing so in newborns.[40] Byrd and colleagues convincingly demonstrated that there are particular auricular deformities in the newborn that are amenable to molding back toward normal.[9] In their publication, the types of deformities that can be most effectively treated and details concerning methods of molding are discussed. Auricular deformations are characterized by a misshapen but fully developed pinna.[65,66] Ear molding techniques are best suited for deformations rather than malformations.[8,12,29,36,41,43,45,59,68,71] Interestingly, approximately one third of the ear deformations that are present at the time of birth self-correct during the first week of life. The patterns of deformation that are frequently seen include the following: prominent/cupped ears; lidded/lopped ears; Stahl (or Spock) ears; helical rim deformities (with an absent or deficient rim); and conchal crus deformities.[49,51,58] Byrd and colleagues found that birth deformations of the auricle more often than not involve the upper third of the ear, with incomplete formation of the superior limb of the triangular fossa being a frequent finding. This leads to a helical rim scapha deformation. The authors stressed the importance of accomplishing three key molding forces to correct the majority of these ear deformations in newborns:

1. A stent or conformer that rests along the retroauricular sulcus and that is in alignment with the antihelix is placed.
2. A second conformer that is curved to match the natural shape of the helical rim is used. It is placed anteriorly but with force directed against the scapha. The anterior conformer is carefully located to avoid excess direct pressure against the posterior conformer for the avoidance of skin necrosis.
3. As the helix is retracted, the molding technique is also used to expand the rim to its full dimension.

The authors described good to excellent results in 90% of the newborns whose external ear deformities were treated in this way. Complications were seen in only approximately 5% of patients and were mostly characterized as localized skin excoriations. The authors recommend withholding earmolding therapy until the end of the first week to identify those infants whose ears spontaneously self-correct soon after birth. It is believed by most that, for treatment to be effective, it should be instituted by the second or (at most) third week

of life. Only approximately half of the infants treated by Byrd and colleagues after 3 weeks of age had good outcomes. The reason for this is believed to be related to the level of hyaluronic acid, which is an important component of ear cartilage.[27] Hyaluronic acid is increased by estrogen and believed to be responsible for the malleable nature of the neonatal ear. The circulating estrogen levels are known to decrease rapidly to levels that are similar to those of older children by 6 weeks of age.[33] It is also known that, with breast-feeding, the maternal transfer of estrogen extends the time frame of higher hyaluronic acid levels, which likely explains the variations in the effectiveness of ear molding in some children; this may also leave the ears prone to relapse after molding treatment is stopped unless the result is maintained.

Conclusions

There are wide variations with regard to what is considered normal for ear size, prominence, and shape. However, when the ears stick out excessively, it may become a source of ridicule and personal anguish for the affected individual. The successful surgical alteration of the prominent ear requires accurate diagnosis; the setting of realistic expectations and the clear communication of those expectations; meticulous operative technique; and careful postoperative management. Attention to detail and a sense for facial aesthetics helps the surgeon to achieve a natural appearance for the reconstructed ear with an acceptable incidence of complications and high level of patient satisfaction.

Patient Education Materials

Otoplasty (Reshaping of the Ears) Surgery

Although a wide variation in the shape and size of the ears naturally occurs from person to person, ears that stick out make individuals easy targets for teasing and ridicule. For most individuals, after this occurs, the sooner this problem is corrected, the better. *Otoplasty* is the name of the surgical procedure that is carried out to diminish ear projection or to change the appearance of the ears. It may be carried out as early as the ears approach their adult size (i.e., around the age of 3 to 5 years) or at any time thereafter. Each individual who is seeking otoplasty has unique concerns. It is important to fully discuss your expectations with your surgeon before surgery.

In general, the technical aspects of the otoplasty procedure include an incision that is made behind each ear to provide access to the ear cartilage. The cartilage of the ear is then reshaped to create improved curvature and position. The procedure is carried out on an outpatient basis with the patient under anesthesia in the operating room. With the ears reshaped and set back, a bandage is used to secure the new ear position and to limit swelling. The bandage generally remains in place for 5 days. After this, return to school or work is rapid. An extra level of care of the ears is required during the initial 4 to 6 weeks of healing.

INSTRUCTIONS FOR OTOPLASTY SURGERY

The purpose of these instructions is to help you prepare for and then recover from otoplasty with as little discomfort and inconvenience as possible.

Preoperative Instructions

1. Do not take any aspirin or aspirin-like products (e.g., Advil) for at least 2 weeks before surgery. Aspirin and aspirin-like products tend to increase bleeding during surgery and bruising postoperatively.
2. Starting 2 days before surgery, we request that you shower and shampoo your hair and wash your face at least once per day. The morning of surgery, shower and shampoo again, if feasible.
3. Do not eat or drink anything after midnight the night before surgery, not even a sip of water.
4. We will give you a prescription for pain control and another for antibiotics to be used after surgery.
5. Be sure to make arrangements with someone to accompany you home after surgery, because you will not be allowed to drive.

Postoperative Instructions

1. It is preferred that you keep the head of your bed elevated when resting and sleeping for the first week after surgery.

2. Take the prescribed antibiotics as ordered and the pain medication as needed.
3. You may eat whatever you wish, but start out slowly, because the anesthesia may leave your stomach unsettled for several hours.
4. Call the office for an appointment on the date specified at the time of discharge.
5. If there are any concerns while you are at home, contact your surgeon's office at any time.
6. Before you arrive for your first office visit after surgery, purchase and bring along an elastic cloth ear band to be used at night when you are sleeping. Your surgeon will instruct you with regard to its use.

Jeffrey C. Posnick, DMD, MD
Director, Posnick Center for Facial Plastic Surgery

Consent for Otoplasty Surgery

_____ Initial here

INSTRUCTIONS

This document has been prepared to help your surgeon to educate and inform you about your otoplasty surgery and its risks as well as alternative treatment options. It is important that you read this document carefully and completely. Please initial each section on each page to indicate that you have read and understand it. In addition, please sign the consent for surgery on the last page as proposed by your surgeon.

_____ Initial here

INTRODUCTION

Otoplasty is a surgical process that is used to reshape the ears. A variety of different techniques and approaches may be used to reshape congenitally prominent ears or to restore damaged ears. Each individual who is seeking otoplasty is unique both in terms of the appearance of his or her ears and his or her expectations of the results that will be obtained with surgery. It is important that you fully discuss your expectations with your surgeon before surgery.

_____ Initial here

ALTERNATIVE TREATMENTS

Alternative forms of management consist of not undergoing an otoplasty operation at all or proceeding with other more limited or more extensive surgical options.

_____ Initial here

RISKS OF SURGERY

Every surgical procedure involves a certain amount of risk. An individual's choice to undergo an otoplasty procedure is based on the comparison of the risk to the potential benefit. Although the majority of patients do not experience the complications detailed below, you should discuss each of them with your surgeon. Make sure that you understand all of the possible consequences of the otoplasty procedure that is planned for you.

_____ Initial here

BLEEDING

It is uncommon to experience significant bleeding during or after otoplasty surgery. If postoperative bleeding does occur, it may require emergency treatment to drain accumulated blood (i.e., hematoma). Do not take any aspirin or similar anti-inflammatory medications for 2 weeks before or after surgery, because this may increase the risk of bleeding.

Continued

_____ **INFECTION**

Initial here Infection is not common after otoplasty surgery. If an infection does occur, treatment that includes the extended use of antibiotics or additional procedures may be necessary.

_____ **CHANGES IN SKIN SENSATION**

Initial here Diminished sensation in the skin of the ear will occur and may not totally resolve after otoplasty surgery.

_____ **TRAUMA**

Initial here Physical injury to the ear soon after otoplasty may disrupt the results of surgery. Care must be taken by you to protect the affected ear from injury during the healing process. Additional surgery may be possible to correct any damage that does occur.

_____ **SKIN CONTOUR IRREGULARITIES**

Initial here Contour irregularities as well as visible and palpable wrinkling of skin and ear cartilage can occur after otoplasty.

_____ **SKIN SCARRING**

Initial here In some cases, excessive scars may result after otoplasty. Scars may be unattractive and of a different color than the surrounding skin. Additional treatments or procedures may be possible to treat unfavorable scarring.

_____ **SURGICAL ANESTHESIA**

Initial here Both local and general anesthesia involve risk. Complications and injuries are possible with all forms of surgical anesthesia and sedation.

_____ **ASYMMETRY**

Initial here The human face is normally asymmetric, and this is especially true for the external ears. Typically, there are differences between ears in terms of shape and size. There will also be variations from one side to the other with regard to the results obtained with an otoplasty procedure.

_____ **DELAYED HEALING**

Initial here Wound disruption or delayed healing is possible after otoplasty. Some areas of the ear may heal abnormally or slowly. Occasionally, further procedures to manage the non-healed tissue may be required.

_____ **ALLERGIC REACTIONS**

Initial here Local allergies to tape, suture material, or topical preparations can occur. Systemic reactions, which are more serious, may also occur in response to the drugs used during surgery and prescription medicines. Allergic reactions may require additional treatment.

_____ **AGING EFFECTS**

Initial here Subsequent alterations in ear appearance may occur as a result of aging or other circumstances not related to the otoplasty surgery.

_____ **RELAPSE**

Initial here As a result of the resilient nature of ear cartilage, relapse (i.e., the springing back out of the ears) may occur after surgery. Revisional surgery may be possible to improve the results if relapse occurs.

_____ **PAIN**

Initial here Infrequently, chronic pain may occur as a result of nerves being injured or trapped in scar tissue after an otoplasty.

_____ **DEEPER SUTURES**

Initial here Deep (buried) non-absorbable sutures may spontaneously work their way through the skin, become visible, or produce irritation and inflammation and thus require removal.

_____ **UNSATISFACTORY RESULTS**

Initial here You may be disappointed with the results of surgery. If so, it may be possible to perform additional surgery to improve your satisfaction.

_____ **ADDITIONAL SURGERY**

Initial here The practice of medicine and surgery is not an exact science. Although good results are expected, there is no guarantee or warranty expressed or implied with regard to the results that may be obtained. If complications do occur, additional surgery or other treatment may be possible.

_____ **HEALTH INSURANCE**

Initial here Most health insurance companies exclude coverage for operations to change the shape of the external ears (otoplasty) or any complications that may occur in association with this surgery. Please carefully review your health insurance subscriber-information pamphlet to clarify these issues.

_____ **FINANCIAL RESPONSIBILITIES**

Initial here The cost of surgery involves several charges for the services provided, including the fees charged by your surgeon (i.e., surgeon's fees); the cost of surgical supplies and the use of the operating room (i.e., facility/hospital charges); and the costs associated with anesthesia (i.e., anesthesiologist's fees). Depending on whether the cost of surgery is covered by your medical insurance plan, you will be responsible for necessary copayments, deductibles, and all other charges that are not covered. Additional costs may occur should complications develop from the surgery. Any secondary surgeries and all charges involved with additional procedures (i.e., surgeon's fees, facility/hospital charges, anesthesiologist's fees) would also be your responsibility.

_____ **DISCLAIMER**

Initial here Informed-consent documents are used to communicate information about the proposed surgical treatment as well as to disclose information about risks and alternative forms of treatment. The informed-consent process attempts to define principles of risk disclosure that should generally meet the needs of most patients in most circumstances.

Because every patient is unique, this informed-consent document should not be considered all-inclusive with regard to defining other methods of treatment to consider and potential risks encountered. Your surgeon will provide you with additional written and verbal information that is based on all of the facts of your particular case and the current state of medical knowledge.

Informed-consent documents are not intended to define or serve as the standard of medical care. Standards of medical care are determined on the basis of all of the facts involved in an individual case and are subject to change as scientific knowledge and technology advance and practice patterns evolve.

CONSENT FOR OTOPLASTY SURGERY

1. I hereby authorize my surgeon, _____, and such assistants as may be selected by my surgeon to perform the following procedure: otoplasty.
2. I have received, read, and understand the following information sheets:
   - Otoplasty (Reshaping of the Ears) Surgery
   - Book chapter about otoplasty
   - Consent for Otoplasty Surgery
3. I recognize that, during the course of the operation and the administration of anesthesia, unforeseen conditions may necessitate different procedures than those stated above. I therefore authorize my surgeon, _____, and my surgeon's assistants or designees to perform such other procedures that are in the exercise of professional judgment necessary and desirable. The authority granted under this paragraph shall include all conditions that require treatment and that are not known to my surgeon at the time that the procedure is begun.
4. I consent to the administration of such anesthetics as are considered necessary or advisable. I understand that all forms of anesthesia involve risk and the possibility of complications, injury, and even death.
5. I acknowledge that no guarantee has been given by anyone with regard to the results that may be obtained from this procedure.
6. I consent to the photographing of me (head and neck region) before, during, and after surgery. These photographs may be used by my surgeon for medical, scientific, or educational purposes now and in the future.
7. For the purposes of advancing medical education, I consent to the admittance of observers into the operating room.
8. I consent to the disposal of any body tissues or medical devices that may be removed.
9. **THE FOLLOWING INFORMATION HAS BEEN EXPLAINED TO ME IN A WAY THAT I UNDERSTAND:**
   - **THE PREVIOUSLY DESCRIBED PROCEDURES TO BE UNDERTAKEN**
   - **ALTERNATIVE PROCEDURES AND METHODS OF TREATMENT THAT I HAVE DECIDED AGAINST**
   - **THE SPECIFIC RISKS AND POTENTIAL COMPLICATIONS OF THE PROCEDURES THAT I PLAN TO UNDERGO**

I CONSENT TO THE PROCEDURES AND THE ABOVE LISTED ITEMS (1 THROUGH 9). I AM SATISFIED WITH THE EXPLANATION GIVEN TO ME.

Aesthetic Alteration of the Soft Tissues of the Neck and Lower Face: Evaluation and Surgery

JEFFREY C. POSNICK, DMD, MD

- Aging of the Facial Soft-Tissue Envelope
- Approach to Rejuvenation Surgery of the Neck and Lower Face
- Facial Aging and Rejuvenation: Treatment Pitfalls
- Conclusions
- Patient Education Materials

I agree with Fritz Barton when he stated the following: "The shape of the human face is composed of a skeletal bony framework that is covered by a soft tissue envelope. Overall, skeletal proportions are probably the most important component of facial attractiveness."[7]

In my experience, the absence of an attractive cervical–mental (neck–mandibular) angle most often is the result of a developmental mandibular deficiency that predisposes the affected individual to loose lower cheek and neck skin, the noticeable bunching of fat in the neck area, and the eventual presence of visible platysma bands that worsens and becomes less attractive with age (see Chapters 19, 23, and 25).

This chapter is not intended to be a treatise that addresses all of the details involved in facial soft-tissue aging and rejuvenation options. Rather, the discussion that follows provides perspective concerning the fundamental importance of the maxillomandibular skeletal structures in the aging process of the neck and the lower face. An approach to the management of the anterior neck soft tissues in specific clinical settings is also described.

Aging of the Facial Soft-Tissue Envelope

Background

The layers of the face encompass the skin; the underlying soft tissues, including the fat (subcutaneous and deep); the mimetic muscles (superficial and deep); the investing fascia, which is known as the *superficial muscular aponeurotic system* (SMAS); the retaining ligaments; and the skeletal structural support system (bones, cartilage, and teeth).[4,18] The soft tissues of the face will naturally descend with age, which will result in progressive laxity and ptosis of the skin, the subcutaneous tissue, the fat, and the fascia (i.e., the SMAS–platysma layer) as well as the retaining ligaments. The facial fat (subcutaneous and deep) may either atrophy (i.e., as a result of resorption) or hypertrophy (i.e., increase in volume), and it is also affected by gravity over time. Facial aging is dynamic and cumulative, and it is also affected by hormonal and degenerative changes in the soft tissues. An understanding of the pertinent biochemical and histologic changes that tend to occur in the facial soft tissues with age and through environmental exposures is an important aspect to consider when developing a reconstruction and rejuvenation treatment plan.

Soft-tissue aging is affected by genetic aspects, hormonal changes, and environmental influences. For some individuals, the deeper soft-tissue envelope remains well preserved while the superficial surface of the skin appears weathered. For others, the surface skin remains youthful while the deeper soft-tissue envelope loses structural landmarks with cutaneous laxity. *Extrinsic (environmental) forces* that are working on the skin include dehydration, inadequate nutrition, temperature extremes, traumatic influences, chronic exposure to strong ultraviolet sunlight, toxins (e.g., cigarette smoke), and gravity. The *intrinsic (genetic) effects* have to do with the individual's basic soft tissues and their skeletal morphology.[15,73] Environmental (extrinsic) factors primarily

result in dysplasia and structural alteration of the dermal and epidermal layers of the skin, whereas intrinsic (genetic) effects on the skin may result in atrophy and the loss of structural dermal and epidermal components.[19,20,29,84] An individual's hormone levels throughout life are also known to have significant effects on the aging process.[30] Aging is associated with declining levels of several hormones, and it is gender dependent. It is known that, in women, declining estrogen levels are associated with cutaneous changes, many of which can be reversed or improved via estrogen supplementation. Studies of postmenopausal women indicate that estrogen deprivation is associated with dryness, atrophy, fine wrinkling, poor healing, and hot flashes.[30,60] Epidermal thinning, declining dermal collagen content, diminished skin moisture, tissue laxity, and impaired wound healing have been reported among postmenopausal women. The soft-tissue effects of changing hormonal levels with age in males are less well studied but presumed to be of equal importance. The cumulative *intrinsic (genetic) effects* on the skin can be seen histologically as epidermal thinning, changes in the morphology of the keratinocytes, and a decrease in the number of Langerhans cells and melanocytes. *Environmental (extrinsic) aging effects* on the skin result in keratinocytic dysplasia and the accumulation of solar elastosis, and they can result in cutaneous carcinogenesis (e.g., basal cell carcinoma, melanoma, squamous cell carcinoma).

All individuals experience some degree of both extrinsic (environmental) and intrinsic (genetic) aging simultaneously (Fig. 40-1). The genetic variability of an individual's skeletal framework and the degree and pace of soft-tissue aging in each tissue layer makes a uniform template for facial rejuvenation impractical. Visually, as the intrinsic and extrinsic aging of the skin progress, there will be pigmentary abnormalities, wrinkles (rhytids), and texture irregularities that may result in a "weathered" appearance. Current thinking about aging also involves the concept that the gain or loss of fat volume within the deep compartments leads to changes in the shape and contour of the face.[20] By contrast, soft-tissue folds occur at the transition points between the thicker and thinner superficial fat compartments. The transition points cause nasolabial folds, labiomental folds, submental creases, and preauricular folds.[65,67] In the upper third of the face, around the eyes, researchers have found that suborbicularis oculi fat is composed of two distinct anatomic compartments: the medial limbus and the lateral canthus region. These researchers have also confirmed that the lateral suborbicularis oculi fat extends from the lateral canthus to the lateral orbital thickening.[7] The deep medial cheek fat is the most medial of the periorbital deep fat compartments.[51] In current clinical practice, periorbital rejuvenation relies more on soft-tissue augmentation and rearrangement than on tissue removal. In the midface, progressive skin laxity is often combined with the resorption of subcutaneous fat and gravitational effects to result in characteristic changes in the soft-tissue envelope.[65] In the lower third of the face, there may be ptosis of the chin soft tissues, a loss of the delineation between the jawline and the neck, the development of characteristic jowls, and looseness in the neck skin (which, in the extreme, is characterized as resembling a "turkey gobble"). In many individuals, prominent vertical platysma bands develop in the submental region, and there is often fat hypertrophy in the submental and submandibular regions. These aging effects further hide or eliminate an otherwise attractive and youthful neck–jaw angle.

Frequent Soft-Tissue Facial Aging Characteristics

- Forehead (horizontal) and glabellar (vertical) creases
- Ptosis (drooping) of the lateral eyebrows
- Redundant upper eyelid skin
- Lower eyelid laxity and wrinkles
- Lower eyelid (puffy) visible bags
- Deepening of the nasojugal grooves and the palpebral malar grooves
- Ptosis (drooping) of the malar soft tissues
- Generalized facial skin laxity*
- Deepening of the nasolabial folds*
- Jowl formation*
- Loss of neck definition (neck–jaw angle) and excess fat collection (hypertrophy) in the neck*
- Deep platysmal bands that are visible in repose and often more obvious with function (e.g., facial expression)*
- Perioral wrinkles
- Downturn of the oral commissures
- Deepening of the labiomental creases

*These are facial soft-tissue aging characteristics that may be more or less improved through traditional face and neck lift techniques.

Basic Principles of Midface and Neck Aging and Rejuvenation

Achieve Facial Harmony

The goal is to help the individual look more like the way they used to look rather than severe, operated on, or unnatural.[44,79,94,95] The recognition of any longstanding maxillomandibular skeletal disharmonies is essential to the achievement of enhanced facial aesthetics. If the surgeon attempts to ignore baseline skeletal deformities and then overcompensates with excessive soft-tissue maneuvers, the outcome is likely to be suboptimal. Amateurish or overdone face lifts often look excessively taut, radically defatted, or overfilled (e.g., fat grafts, artificial fillers), or they may involve irregularities from deep layer soft-tissue manipulation. The "overoperated" face may also look startling and unnatural from too much soft-tissue surgical alteration in just one region or layer of the face while ignoring the others. The entire face and all of its layers should be analyzed and given consideration before focusing on just one aspect or technique for rejuvenation.

• **Figure 40-1** A 46-year-old woman first arrived for the surgical assessment of a long-standing bony mass in the left forehead region. She underwent a computed tomography scan that confirmed an osteoma without intracranial involvement. She elected to not undergo biopsy, recontouring, or removal at that time. She returned 13 years later, when she was 59 years old, to discuss facial aging. Her concerns included webbing (platysma bands) and loose skin of the neck; heavy jowls; marionette lines; deep nasolabial folds; puffiness and irregularities of the lower eyelids; hollowing in the temporal and cheek regions; deepening of the labiomental crease; and vertical wrinkles of the upper lip. She had undergone Restylane injections of the nasolabial folds, the marionette lines, the labiomental crease, and the lower eyelids with another clinician but without satisfactory improvement. She also had a short face growth pattern (i.e., maxillomandibular deficiency). During her teenage years, she had undergone camouflage orthodontic treatment that included upper bicuspid extractions to achieve a neutralized occlusion. There was no dental show with the upper lip in repose. With broad smile, only half of the maxillary incisors were visible. The upper lip appeared to have lengthened slightly, and the lips appeared to be more deflated (as compared with images taken when the patient was 46 years old). She stated that she received frequent comments about looking "sad" or "unhappy." She had a history of an inability to breathe well through the nose, loud snoring, restless sleeping, and excessive daytime fatigue. An attended polysomnogram was carried out and confirmed obstructive sleep apnea, with a respiratory disturbance index of 24 events/hour with desaturations of up to 85%. A comprehensive approach to improve dental health, open the upper airway, and enhance facial aesthetics was planned (see Chapters 23 and 25). **A,** Frontal facial views at 46 and 59 years of age. **B,** Oblique facial views at 46 and 59 years of age. **C,** Profile facial views at 46 and 59 years of age.

Achieve Volume Redistribution rather than Skin Tension

Throughout the body, the soft tissues external to the skeleton are anchored to the bony framework by osseocutaneous ligaments that pass directly from the dermis to the periosteum in bare areas where there are no muscles that separate them.[22,39,49,62,63,67,80] The most prominent of these retaining ligaments in the head and neck are in the cheek and along the lateral border of the mandible. The retaining ligaments that partition the cheek fat from the neck are called the *mandibular septum*. A face lift that simply undermines the cheek soft tissues followed by excessive skin resection and then wound closure under tension does not simultaneously manage the deeper soft tissues. Therefore, in these circumstances, skin undermining and resection alone will rarely achieve an attractive or youthful face. This limited "skin-only" approach to face lifting with excessive skin resection may also lead to unsightly scars, flap necrosis, or, more commonly, distortions of key landmarks with the loss of the natural facial curvatures. The use of face-lift techniques that also modestly redistribute the deep soft-tissue layers (i.e., the SMAS–platysma layer) in combination with conservative skin removal and relaxed wound closure will often result in the more pleasing contours that are associated with a youthful and attractive appearance.

Recognize the Presence of Fat Atrophy and Hypertrophy

The process of aging involves not only gravitational effects on the soft tissues and degenerative changes of the skin but, in many cases, noticeable soft-tissue volume loss (deflation) through the atrophy (resorption) of the fat.[10,29,42,66,68,70,72,81] Frequent visual effects of descent in the face include the deepening of the nasolabial folds, ptosis of the malar portion of the superficial fat, and the accumulation of fat in the jowls. The classic effects of deflation are seen most frequently in individuals who have had lifelong thinness of the face. The fat atrophy in these individuals is often visually seen in the temporal fossa, periorbital, buccal, and perioral regions. In other individuals, a pattern of simultaneous face and neck fat hypertrophy as a result of weight gain will occur with age. To avoid an amateurish face lift, a good general rule for the surgeon to follow is to only cautiously remove any fat above the inferior border of the mandible and to be sure that an appropriate amount of fat is removed below the mandibular inferior border. Although adding fat to atrophied regions of the face is beneficial in principle, in many individuals, the long-term success of these techniques (i.e., autogenous fat grafting or the use of artificial fillers) to achieve a natural-appearing rejuvenation remains a work in progress.[10]

Recognize Degenerative Changes in the Skin

Face lifting will address gravitational changes in the soft-tissue envelope, but it does not have an effect on the quality of the soft tissues themselves.[60,85] Face-lift procedures will not treat wrinkles (rhytids), sun damage, creases, or age-related pigmentation. If feasible, fine wrinkles and irregular pigmentation are treated with good-quality skin care and possibly resurfacing procedures (e.g., dermabrasion, chemical peel, laser). Preventative measures of avoiding excessive ultraviolet light exposure, cigarette smoke, temperature extremes, dehydration, and nutritional deficiencies are important.

Recognize the Negative Effects of Any Baseline Maxillomandibular Skeletal Disharmony

Significant variation occurs in the aging of each individual's face and neck. Recognition that the shape of the neck is fundamentally determined by the maxillomandibular skeleton is essential (Figs. 40-1 through 40-4).[13,16,24,32,69,71,93] The ideal neck configuration requires a well-proportioned facial skeleton; it is often described as having a cervical–mental (neck–jaw) angle of 105 to 120 degrees and a distinct mandibular inferior border. Interestingly, despite various assertions and opinions by a handful of authors, in the absence of a loss of the teeth or significant alteration of the dentition through either natural attrition or dental restorative procedures, no convincing data confirms significant changes in the maxillofacial skeleton with aging (see Chapter 25).*

Approach to Rejuvenation Surgery of the Neck and Lower Face

Traditional Face-Lift Approach to Rejuvenation

Face lifting was first performed during the early 1900s and involved skin incisions around the ears, limited skin-flap undermining, and then skin excision before wound closure. In 1859, Gray defined a unique deep layer of tissue just below the facial skin that was described as "superficial subcutaneous fascia." Not much changed until the 1970s, when both Tessier and Skoog independently described the aesthetic benefit of manipulating this superficial subcutaneous fascia as a separate component during face lifting for rejuvenation purposes. The superficial subcutaneous fascia was recognized as investing the platysma muscles and fusing to the parotid fascia as the facial extension of the cervical investing fascia. It later came to be called the *superficial muscular aponeurotic system* or *SMAS,* as mentioned previously.[48] The SMAS envelopes the platysma muscles within the neck and the lower cheek region. Superiorly, it terminates as the investing layer of the superficial mimetic muscles. Laterally, it fuses with the parotid capsule. Superiorly, it passes over the zygomatic arch to join the temporoparietal fascia. Tessier and Skoog were the first to include as part of the face-lift technique not just the undermining and excision of the skin but also the management of the so-called SMAS–platysma layer. This required unique incisions, undermining, redraping, and tightening of the SMAS–platysma as part of the face-lifting procedure. Since the initial contributions of Tessier and Skoog, every conceivable recommendation has been made by surgeons for dissecting,

• **Figure 40-2** A woman in her mid 50s was referred from her general dentist to an orthodontist for the management of a longstanding Angle Class II excess overjet malocclusion that had gradually resulted in deterioration of the posterior dentition. The orthodontist recognized that the malocclusion resulted from a retrusive mandible and a constricted maxilla. With referral for surgical evaluation, the patient was found to have a developmental jaw deformity, chronic obstructed nasal breathing, and a sleep history that was consistent with obstructive sleep apnea. Unfavorable facial aging with a desire for an improved neck–chin angle was also discussed. An attended polysomnogram confirmed moderate obstructive sleep apnea. The patient agreed to proceed with orthodontic treatment that included lower first bicuspid extractions to relieve dental compensation in combination with jaw, intranasal, and facial surgery. The objectives were to open the upper airway, enhance the facial aesthetics, and achieve improved long-term dental health. The patient's surgical procedures included maxillary Le Fort I osteotomy in segments (horizontal advancement, counterclockwise rotation, arch expansion, and correction of the curve of Spee); bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement); anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication); and septoplasty and inferior turbinate reduction (see Fig. 25-1). **A,** Profile views before and after reconstruction. Note the improved A-point–to–B-point relationship that was achieved as a result of maxillomandibular counterclockwise rotation. **B,** Articulated dental casts that indicate analytic model planning. **C,** Lateral cephalometric radiographs before and after surgery. Note the improved posterior airway space with pharyngeal expansion as a result of the orthognathic procedures.

• **Figure 40-3** A woman in her early 50s was referred by a prosthodontist for surgical evaluation. There had been a gradual deterioration of the dentition, at least partially as a result of the longstanding skeletal Class II excess overjet deep-bite malocclusion. Head and neck evaluation confirmed a retrusive mandible that also resulted in retroglossal airway obstruction. A desire for improved profile aesthetics was also discussed. A comprehensive approach to dental rehabilitation, opening the upper airway, and facial rejuvenation and reconstruction was selected. Coordinated endodontic, orthodontic, periodontic, prosthodontic, and surgical care was required. Periodontal treatment, extractions, dental implant placement, restorative temporization, and orthodontic alignment were carried out. This was followed by surgery that included bilateral sagittal split ramus osteotomies (horizontal advancement and counterclockwise rotation); osseous genioplasty (vertical lengthening) with interpositional grafting; and an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication). This was then followed by crown lengthening and final dental restorations (see Fig. 25-6). **A,** Profile views before and after reconstruction and dental rehabilitation. **B,** Oblique facial views before and after reconstruction and dental rehabilitation.

• **Figure 40-4** A woman in her mid 50s was seen by a prosthodontist for the management of a deteriorating posterior dentition. She was confirmed to have secondary dental trauma as a result of a longstanding malocclusion. She was referred to an orthodontist and then for surgical assessment. Head and neck evaluation confirmed a short face growth pattern with a Class II excess overjet deep bite and constricted maxillary arch malocclusion. She had a lifelong history of obstructed nasal breathing, and her history was suggestive of obstructive sleep apnea (this was confirmed with an attended polysomnogram). Facial aesthetic concerns included downturned corners of the mouth, deep perioral creases, early jowl formation, weak profile, an obtuse neck–chin angle, and loose skin around the neck. The patient agreed to a comprehensive surgical and dental rehabilitative approach. Periodontal evaluation, initial restorations, and orthodontic decompensation preceded surgery. The patient's surgical procedures included maxillary Le Fort I osteotomy (horizontal advancement, counterclockwise rotation, and vertical adjustment); bilateral sagittal split osteotomies of the mandible (horizontal advancement and counterclockwise rotation); osseous genioplasty (horizontal advancement); an anterior approach to the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication); and septoplasty, inferior turbinate reduction, and nasal recontouring (see Fig. 25-7). **A,** Oblique facial views before and after treatment. **B,** Profile views before and after treatment.

undermining, excising, adding to, or removing virtually all of the tissue layers and cell types in the head and neck to further enhance the aesthetic outcome.[2-5,8,18,21,31,47,50,59,77,78] Many of the "innovations" in the area of face lifting have proven to have little additional long-term value, and some have resulted in increased complications and prolonged recoveries. This was confirmed by Chang and colleagues in a recently completed systematic review and comparison of efficacy and complication rates among a variety of face-lift techniques. The authors conclude that there are pros and cons to each of a variety of face-lift techniques and that there is no clear evidence that one is routinely superior to another.[9]

A well-designed traditional face lift often confers much benefit to the jowls (i.e., the mandibular line) and the neck (Figs. 40-5 through 40-10). It can be an effective way to soften the nasolabial folds, to lift the jowls back into the face, to relieve the platysmal bands, to remove the loose skin and excess fat of the neck, and to restore the neck–jaw angle back to its baseline. This can change the overall facial shape from rectangular back to that of a heart in a way that no other soft-tissue treatment modality can provide. The basic

• **Figure 40-5** A woman in her early 50s arrived for the evaluation of facial aging. She had satisfactory skeletal proportions and no significant surface skin layer aging effects. She requested surgery to diminish her jowls, to soften her nasolabial folds, and to reduce the amount of loose skin in her neck region. She underwent a face lift that included periauricular and submental incisions; cheek and neck flap elevation; superficial musculo-aponeurotic system flap elevation with postauricular transposition; neck defatting; vertical platysma muscle plication; and skin resection and redraping. Asymmetric upper eyelid ptosis was not addressed. **A,** Oblique facial views before and after surgery. **B,** Profile views before and after surgery.

traditional face-lift approach requires the consideration of the following:

- *Skin incision placement* (i.e., preauricular with temporal extensions and postauricular with occipital extensions)
- *Skin flap elevation and undermining* (i.e., temporal, cheek, postauricular, neck, and submental regions)
- *Supraplatysmal, intraplatysmal, and subplatysmal defatting* (e.g., below the inferior border of the mandible and chin, above the thyroid cartilage, and anterior to and above the sternocleidomastoid muscles)

• **Figure 40-6** A 50-year-old woman arrived for the evaluation of facial aging. She has satisfactory skeletal proportions and minimal skin surface layer aging effects. She underwent a limited incision brow lift with suspension; blepharoplasty (elliptical excision of the upper eyelid skin and redraping of the lower lid tissue); and a face lift as described in the legend for Fig. 40-5. **A,** Oblique facial views before and after surgery. **B,** Profile views before and after surgery.

• **Figure 40-7** A woman in her late 50s arrived for the evaluation of facial aging. She had satisfactory skeletal proportions but marked surface layer aging effects. She elected to not undergo skin resurfacing procedures. She agreed to a limited incision brow lift with suspension, blepharoplasty (elliptical excision of the upper lid skin and lower lid redraping), and a face lift as described in the legend for Fig. 40-5. **A,** Frontal views before and after surgery. **B,** Oblique facial views before and after surgery. **C,** Profile views before and after surgery.

• **Figure 40-8** A woman in her early 40s requested an improved neck–chin angle and the relief of hooding of the upper eyelids. She had a short face growth pattern that resulted in mildly deficient lower anterior facial height and horizontal facial projection. She had a good airway and occlusion. There was limited surface skin layer damage and aging effects. She underwent upper blepharoplasty (elliptical skin incision) and a face lift as described in the legend for Fig. 40-5. **A,** Oblique facial views before and early after surgery. **B,** Profile views before and early after surgery.

- *Platysma muscle management* (i.e., vertical plication versus the excision of bands)
- *SMAS management* (i.e., preauricular SMAS plication versus SMAS elevation with postauricular flap transposition)
- *Redraping of the elevated skin flaps* (i.e., in a superoposterior vector)
- *Excision of redundant skin* (e.g., temporal, preauricular, postauricular, occipital)
- *Wound closure* under minimum tension

Anterior Neck (Submental) Approach to Rejuvenation

Background

Changes that occur in the neck with age can alter the natural youthful facial curvatures and angles.* As people age, characteristic changes tend to occur in the skin and throughout the soft-tissue envelope. Soft-tissue

• **Figure 40-9** A woman in her early 50s with facial aging concerns. She had a mild long face growth pattern but a satisfactory occlusion. The lower anterior facial height was slightly increased, which resulted in mild lip incompetence and mentalis strain; this resulted in accentuated perioral creases. She agreed to blepharoplasty (elliptical excision of the upper lid skin and redraping of the lower lid tissue); osseous genioplasty (vertical reduction and horizontal advancement); and a face lift as described in the legend for Fig. 40-5. **A,** Frontal views before and after surgery. **B,** Profile views before and after surgery. Note the relief of the perioral folds and the mentalis strain as a result of vertical reduction and advancement genioplasty.

rejuvenation procedures that focus on the neck often include the following: 1) cervical flap elevation; 2) the selective removal of fat (above, in between, and below the platysma muscles); 3) the tightening of the platysma muscles (in the neck midline); and 4) the redraping of lax skin (i.e., skin retraction). In the presence of well-proportioned (harmonious) maxillomandibular skeletal structures, the combination of these procedures can generally be carried out to achieve a preferred geometric angle between the cylindrical neck and the straight-line inferior border of the jaw.[12,18,23,25-27,34-36,41,46,61,83,94,95]

Aging of the neck often presents in one of two classic ways; it is primarily a reflection of the underlying skeletal anatomy. One common pattern is what appears to be a *long neck with a sharp neck–jaw angle.* This occurs in an individual with preferred proportions and fullness of the jaws. With aging, these patients may develop visible platysmal bands but with the maintenance of a reasonable neck–jaw angle and chin projection. A second common pattern of presentation is seen in individuals with what appears to be a *short neck and a poorly defined neck–jaw angle.* This is the result of a baseline mandibular deficiency (e.g., combined

Orthognathic Surgery; J.C. Posnick

• **Figure 40-10** A woman in her late 50s arrived for the evaluation of facial aging. She had satisfactory skeletal proportions and occlusion. Her skin was thick but did not have major ultraviolet light damage. She agreed to a limited incision brow lift with suspension; blepharoplasty (elliptical excision of the upper eyelid skin and fat removal and redraping from the lower lids); and a face lift as described in the legend for Fig. 40-5. **A,** Frontal views in repose before and after rejuvenation. **B,** Frontal views with smile before and after rejuvenation.

• **Figure 40-10, cont'd C,** Oblique facial views before and after rejuvenation. **D,** Profile views before and after rejuvenation.

maxillomandibular deficiency, primary mandibular retrognathia, or a long face growth pattern with sagittal deficiency and clockwise rotation of the maxillomandibular complex; see Figs. 40-2, 40-3, and 40-4). Individuals with this type of neck experience facial aging prematurely and in a more detrimental way. In the presence of sagittal deficiency of the mandible, when any degree of neck soft-tissue laxity occurs and even with small amounts of submental and supraplatysmal fat accumulation, further loss of the clear separation between the chin and neck (i.e., an obtuse neck–jaw angle) can be expected. Skeletal (orthognathic) procedures to reconstruct the jaws toward Euclidean proportions will have a dramatic positive effect on the facial aging of this latter group of individuals (see Figs. 40-2, 40-3, and 40-4). Completing traditional face and neck soft-tissue lifting procedures alone in the presence of a deficient maxillomandibular skeletal framework can be disappointing and, in some cases, disastrous. The surgeon should view the overlying soft-tissues as just the icing on the cake and not as the cake itself. The failure to recognize these anatomic realities is responsible for much clinician frustration and many suboptimal "face-lift" results.

A fundamental clinical observation is that the visual appearance of aging in the neck is greatly influenced by the baseline maxillomandibular skeletal anatomy. The ideal horizontal mandibular plane relative to the vertical cylindrical neck (i.e., an angle of 105 to 120 degrees) will abnormally slump downward and backward when the mandibular skeletal framework is deficient and clockwise rotated (i.e., long face growth pattern; see Chapter 21).

An example of the negative effects of the skeleton on the soft-tissue surface anatomy is seen in the presence of primary mandibular deficiency with excess overjet (see Chapter 19). Not only will the lower lip be flaccid with a deep labiomental fold (curl), but the soft tissues directly over the bony chin are bunched and ptotic, and the soft-tissue structures of the neck are cramped together to result in a double (soft-tissue) chin. In the presence of mandibular deficiency, the chin seems to fall directly into the neck without any semblance of a normal "right-angle" curvature (see Fig. 40-2, *A* and *B*).

When both the maxilla and the mandible lack vertical height and horizontal projection (i.e., short face growth pattern; see Chapter 23), the cheeks often appear to be puffy. There will be deep nasolabial folds, heavy jowls, perioral creases, and downturned oral commissures that compound the negative effects of the observed obtuse neck–jaw angle.

The deficient maxillo-mandibular skeletal anatomy seen in the adult, as described above, will have been present since the teenage years; however, it appears to be more aesthetically objectionable with aging as the overlying soft tissues progressively lose tone and become lax.

Patient Selection

The best candidates for a *neck lift through a limited submental incision* are those with a harmonious and proportionate maxillomandibular skeleton and those who do not require or request soft-tissue rejuvenation above the mandibular border or angle. A thorough evaluation by the surgeon followed by a realistic discussion with the patient is required to clarify these issues. To avoid an unhappy patient after surgery, any limitations of an anterior (submental) neck-lift approach should be clarified in advance.

Appropriate patient selection (i.e., for a traditional face lift versus an anterior submental neck lift) is based primarily on the degree of skin laxity. Zins proposed a useful grading scale for neck skin laxity: Grade I (no laxity); Grade II (mild laxity); Grade III (moderate laxity); and Grade IV (severe laxity)[95]:

- *Grade I* patients may only require closed liposuction. However, even Grade I patients frequently benefit from an open approach to fully access and then remove subplatysmal fat.
- *Grade II* patients are good candidates for an anterior (submental) approach to neck rejuvenation. Their limited lax skin should be expected to retract in a favorable way.
- *Grade III* patients can often be managed with an anterior (submental) approach to the neck. They will require wide cervical flap elevation with meticulous attention to release all septae and ligaments to achieve maximum skin retraction and to avoid unfavorable visible irregularities after surgery. Full disclosure with regard to the limitations of an anterior neck lift and the setting of realistic expectations are especially relevant for the Grade III patient to avoid later disappointment.
- *Grade IV* patients are not good candidates for an anterior-only approach to the neck and should be considered for a traditional face lift. Unless skin is excised (i.e., with a traditional face-lift approach), residual laxity will provide a suboptimal result.

Cervical Flap Elevation and Neck Defatting

Some teenagers and young adults and many middle-aged adults benefit aesthetically from neck defatting.[1] The fat removal is typically carried out in the region below the inferior border of the mandible, above the thyroid cartilage, and anterior to the sternocleidomastoid muscles. Whether by liposuction, direct scissors excision, or a combination of the two the objective is to remove appropriate adipose cells deep to the skin and superficial to the platysma muscles. Below the chin in the midline, where there is a tendency for the separation of the platysma muscles, excess fat also frequently accumulates. If the platysma muscles are in continuity (i.e., if there is no dehiscence), then surgical separation is required to expose the excess submental fat for removal.

Closed neck liposuction without skin-flap undermining is preferentially carried out only in those patients with no skin laxity and minimal excess neck fat and who do not require platysma separation to remove submental fat. This situation is more commonly seen in teenagers and young adults. In all other patients, cervical flap elevation is completed first.

Generally, the *cervical skin undermining* extends up to the inferior border of the mandible and chin, laterally to and over the surface of the sternocleidomastoid muscles, and inferiorly past the thyroid cartilage toward the clavicles. In those with only moderate skin laxity, adequate release of all cutaneous septae and cutaneous ligaments will generally allow for skin contracture during healing without the need for skin resection. After surgery, skin irregularities and adhesions will persist if inadequate undermining was accomplished. A second procedure would then be required to complete the undermining. The surgeon should also avoid uneven fat removal and excessive defatting in the neck, because this can result in contour irregularities between the skin and the platysma muscles. Ptotic submandibular salivary glands may also affect an otherwise satisfactory result. This author does not favor either partial submandibular gland resection or intracapsular gland dissection and repositioning, because the incidence of associated complications is high.[28,76,82] Close to the midline and just below the chin, overaggressive fat removal may result in an unnatural concavity, which is a stigma of an amateurish cervical defatting. In some cases, prominent hypertrophy digastric muscles may benefit from "shaving" (i.e., scissors excision) in the region just below the chin.[11]

Management of the Platysma Muscles and Cervical Fascia

The *platysma muscles* are enveloped by the cervical investing fascia on each side. The muscles run from just over the inferior border of the mandible (i.e., the lower cheek) and down to and over the clavicles across the curve of the neck. With contracture, the muscle fibers shorten and bowstring (i.e., form vertical bands) away from the midline of the neck. This bowstringing tendency is restrained by the cervical investing fascia. In most individuals, the thin midline cervical fascia tends to attenuate with age; this explains the fascial dehiscence with a pulling away of the platysma muscle on each side from the neck midline that is observed later in life. Initially, bowstrings are only present with active contraction; eventually, however, passive platysmal banding is observed.

A *platysmaplasty* can be a useful component of neck rejuvenation. Through a 3- to 4-cm incision that is made adjacent to a natural submental crease, subcutaneous undermining is performed that allows for the separation of the neck skin from the platysma muscles. The extent of cervical flap elevation should be dependent on the degree of skin laxity. Even after flap elevation, there are limits to the skin's ability to redrape during healing without irregularities or residual laxity. Those with greater skin laxity (i.e., Grade IV patient and some Grade III patients) are not good candidates for an anterior (submental) neck approach, as discussed earlier in this chapter.

Most individuals who require platysmaplasty will also benefit from neck region fat removal being carried out simultaneously. This includes *supraplatysmal defatting* out to the sternocleidomastoid muscles and down to the thyroid cartilage as well as *intraplatysmal* and *subplatysmal defatting* below the chin as described previously.

After cervical flap elevation and appropriate defatting, the medial border of each platysma muscle is identified and joined in the midline with the use of a series of interrupted sutures. The *vertical platysma plication* extends from just above the thyroid cartilage to approaching the bony chin. Some surgeons prefer a continuous running suture; however, this author believes that such a suture is more likely to result in vertical ridging. As long as the lateral cervical investing fascia remains reasonably tight, elevation of the neck sling can be accomplished through this anterior (submental) approach, without the need for a simultaneous traditional face lift (i.e., preauricular and postauricular incisions, cheek flap elevation, lateral SMAS tightening, and skin excision). Nevertheless, a traditional face-lift approach remains the best way to maximize neck tightening, because skin removal is also possible.

The *anterior (submental) neck approach* is preferred to a *traditional face lift* in individuals with reasonable skin elasticity who are not overly concerned about the aging of their cheek region (i.e., aging of the jowls and the nasolabial folds). An anterior submental approach will not satisfy individuals who need and expect improvements in the frontal view (i.e., a reduction of the jowls, a softening of the nasolabial folds, and the management of the malar and eyelid regions) or in those with moderate or greater degrees of neck skin laxity.[94,95]

Anterior Neck (Submental) Approach: Step-By-Step Surgical Technique (Fig. 40-11) (Video 16)

Positioning on the Operating Room Table

- Place the patient supine on the operating table with his or her head on the Mayfield horseshoe in the neutral neck position.

Anesthesia

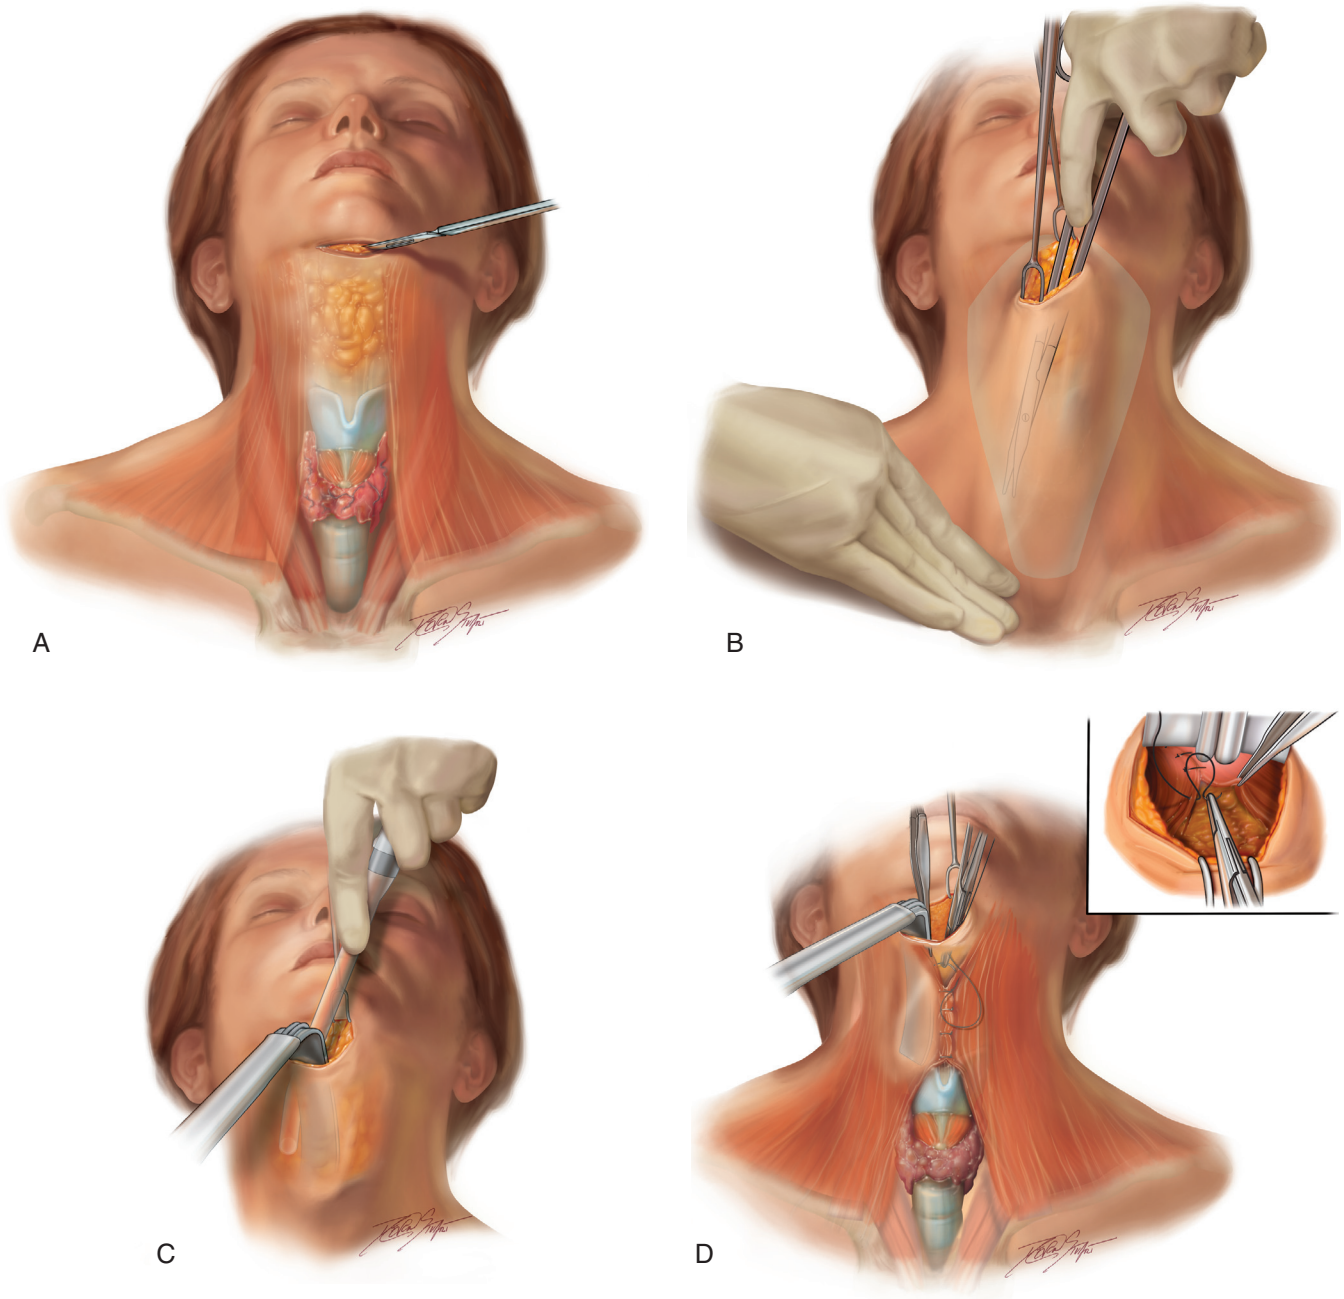
- When the procedure is carried out in conjunction with orthognathic surgery, general anesthesia is administered through a nasotracheal cuffed (RAE) tube. The nasotracheal tube will already have been secured to the cartilaginous septum with suture (#0 Ethibond).
- The application of ophthalmic eye ointment and the insertion of corneal shields deep to the eyelids will also already have been performed.

Medications

- Administer intravenous antibiotics (Cefazolin 17 mg/kg/dose, max: 1 gm).
- Administer steroids via an intravenous bolus (Dexamethasone 0.5 mg/kg/dose, max: 8 mg).

Preparation and Draping

- After the completion of the orthognathic procedures (including the removal of the throat pack and the placement of interocclusal elastics), the patient is reprepped,



• **Figure 40-11** Illustrations that demonstrate the anterior (submental) approach for neck rejuvenation as described in the text. **A,** Illustration of the neck region in the operating room in preparation for an anterior (submental) rejuvenation procedure. The submental incision is marked. A knife (no. 15 blade) is used to initiate the skin incision. Important underlying landmarks are indicated, including the thyroid cartilage; the sternocleidomastoid muscle on each side; the platysma muscles with central dehiscence; and the accumulated fat. **B,** Illustration that demonstrates the elevation of the cervical flaps after the completion of the submental incision. Instruments that are in place include double skin hooks with one at each side of the submental wound. The assistant's hands are positioned over the clavicle to provide counter tension to the double hook located at the submental incision. In this way, the neck skin in the region of the cervical flap elevation is taut. A Stevens scissors is then used to complete the dissection in the exact location where the neck skin is placed under tension. The green shaded area indicates the extent of planned supraplatysma dissection for cervical flap elevation. **C,** Illustration after cervical flap elevation that demonstrates liposuction in progress. A no. 7 curved plastic cannula is used in the supraplatysma plane laterally and in the subplatysma in the midline below the chin. **D,** Illustration that demonstrates vertical platysma muscle plication in progress. A lighted retractor is in place to provide exposure for the direct visualization of the platysma muscle dehiscence. The surgeon uses a long needle driver and a long forceps to place interrupted sutures (3-0 Vicryl) for the achievement of vertical platysma muscle plication. There is also a close-up illustration of the wound with a lighted retractor in place. The long forceps elevates the edge of the platysma muscle on the right side. A needle driver is used to place a suture through the elevated platysma edge. Several interrupted sutures are already in place from just above the thyroid cartilage.

and additional sterile drapes are placed over the ones that are already there.
- Reprep entire neck below the clavicles, the face, and the postauricular regions with the use of Betadine solution (do not use soap, alcohol, Hibiclens, and so on).
- Draping is completed with exposure of the neck just inferior to the sternal notch and clavicles. Exposure of the entire neck, the external ears, and the lower face is also accomplished.

Instrumentation
- New sterile gloves are provided to the operating team.
- New sterile instrument sets are opened.

Surgical Markings
- Locate and use a surgical pen to mark the extent of planned cervical flap elevation, including the following:
  - The inferior border of the mandible and the chin
  - The anterior border of the sternocleidomastoid muscles
  - The thyroid cartilage and below toward the clavicles
- Locate and use a surgical pen to mark the proposed 3- to 4-cm submental incision.

Local Anesthesia
- Injection 50 mL of tumescent solution (epinephrine 1:1000, 1 mL; bupivacaine plain, 10 mL; 0.9% sodium chloride, 500 mL) within the designated surgical field. The injection is made below the skin and above the platysma muscles.

Submental Incision
- Use a knife (no. 15 blade) to complete the 3- to 4-cm submental incision.

Elevation of the Cervical Flaps
- A wide double skin hook is placed on either side of the complete submental incision. With the use of the skin hooks spreading in opposing directions, tension separates the wound.
- A long Stevens scissors is used to elevate the cervical flaps. Stretch-tension is achieved on the skin of the cervical flap to be elevated; this is accomplished with the double skin hook at the submental wound and the assistant's hands over the neck skin above the clavicle. The Stevens scissors is then used to blindly separate the skin and the subcutaneous flap from the underlying platysma muscles throughout all planned locations on both sides of the neck.
- The dissection continues down past the thyroid cartilage toward the clavicles and laterally just above the anterior border of each sternocleidomastoid muscle.
- The dissection continues superiorly to the inferior border of the mandible. Caution is used to avoid injury to the marginal mandibular branch of cranial nerve VII.
- The lighted retractor is then used to confirm the complete release of the cervical flaps from all cutaneous septae and cutaneous ligaments.
- The lighted retractor is also used to confirm adequate hemostasis. A guarded electrocautery device is used to control any bleeding vessels.

Defatting Above, in Between, and Below the Platysma Muscles
- Supraplatysma defatting is carried out via open liposuction with the use of a no. 7 curved plastic cannula.
- With the use of a lighted retractor under direct vision, any remaining clumps of fat are extracted via either liposuction or sharp scissors removal.
- If the platysma muscles are intact (i.e., without dehiscence), they are separated in the midline just below the chin to expose the submental fat pad.
- Subplatysmal fat is removed with the use of open liposuction via a no. 7 curved plastic cannula or sharp scissors excision.
- In the interdigastric space, fat is removed or resected to be flush with the anterior digastric bellies.
- If there is prominent elevation of the digastric muscles, the edges are resected with a scissors.

Platysmaplasty
- Consideration is given to tightening the platysma muscle sling. Dehiscence of the muscles in the midline may be seen from the thyroid cartilage below to the bony chin above.
- The lighted retractor is useful to directly visualize the platysma muscles.
- Vertical platysma muscle plication is carried out with interrupted sutures (3-0 Vicryl).
- Typically, eight to ten interrupted sutures are placed.

Skin Closure
- Before wound closure, the redraped cervical flaps are inspected to confirm the absence of irregularities caused by residual attached cutaneous septae or cutaneous ligaments.
- The wounds are again inspected with the lighted retractor and the electrocautery device to confirm adequate hemostasis.
- If oozing is poorly controlled, consideration is given to the placement of a suction drain.
- The fascia layer of the submental wound is closed with interrupted sutures (5-0 Vicryl).
- The skin edges are approximated with running suture (6-0 nylon).

Placement of Dressing
- A mildly compressive chin and neck dressing is placed (e.g., a Jobst neck/chin strap).

Postoperative Care
- Two days after surgery, the chin/neck dressing is removed, and the patient is allowed to shower (including the head and neck region) and shampoo the hair. The dressing is replaced by the patient for an additional 3 days.

- The dressing is removed daily for showering and then replaced until 5 days after surgery.
- Submental sutures are removed on the fifth postoperative day.
- Antibiotics are discontinued after 5 days.
- No sports participation or direct facial trauma is allowed for 5 weeks.

Complications and Unfavorable Results

Hematoma

The incidence of hematoma with an anterior (submental) neck approach using the techniques described in this chapter is not common. The use of a lighted retractor confirms satisfactory hemostasis under direct vision at operation. Proper patient selection (i.e., non-hypertensive, not taking platelet-inhibiting medications or supplements) and a smooth emergence from anesthesia (i.e., control of blood pressure and vomiting) are also essential. A compression dressing as described is helpful to limit swelling after surgery. This author has not found it necessary to routinely place drains.

Skin Necrosis

The incidence of skin necrosis in properly selected patients and with the use of sound flap elevation techniques is uncommon. The occurrence of flap necrosis may be significantly higher in those with vascular occlusive disorders and in smokers (see Chapters 16 and 25).

Infection

Wound infection is not common after neck lift surgery as described in this chapter. The use of perioperative antibiotics is indicated. Close postoperative communication between the surgeon and the patient is essential to ensure prompt treatment if infection does occur. Infection is treated with appropriate antibiotics and drainage procedures.

Nerve Injury

The incidence of facial nerve injury (i.e., of the marginal mandibular branch) is low as long as the field of dissection remains below the inferior border of the mandible and above the platysma muscle laterally.

Skin Irregularities

Skin irregularities are primarily the result of inadequate cervical flap undermining with the incomplete release of all cutaneous septae and cutaneous ligaments extending the borders of flap dissection. In properly selected cases and with the complete release of septae and ligaments, neck skin has the unique ability to contract without the need for resection. However, those individuals with moderate or greater degrees of laxity before surgery cannot be expected to achieve optimal results without skin excision (i.e., a traditional face-lift approach). Irregularities may also result from a hematoma that is slow to resolve. Skin irregularities related to inadequate undermining that persists are managed secondarily by extending the degree of undermining.

Contour Irregularities

Contour irregularities may result from underresection, overresection, or the removal of supraplatysmal subcutaneous fat. When this does occur, it is generally seen either low in the neck toward the thyroid cartilage or laterally toward the sternocleidomastoid muscles. The removal of retained fat is managed secondarily with surgery; this is easier to deal with than areas of overresection that require grafting.

Midline Ridging

Midline ridging after vertical platysma muscle plication may occur with the extensive use of non-resorbable sutures in the presence of very thin overlying skin. This author believes that the placement of a continuous running suture (rather than individual interrupted sutures) may be more likely to result in ridging. In those few circumstances in which significant midline ridging occurs, secondary surgery with suture removal and platysma recontouring may be beneficial.

Residual Submental Fullness or Hollowing

Subplatysma midline defatting is carried out to reduce excess fullness. After the separation of the platysma muscles, defatting down to the level of the digastric muscles is usually beneficial.[11] If residual fullness remains as a result of inadequate fat removal, this can be managed secondarily to finish the job. Excessive defatting in this region often creates a submental hollow with a resulting "operated" look. Secondary grafting may be beneficial.

Visible Unsightly Digastric Muscle Ridging

Partial resection (shaving) of the digastric muscles is not typically necessary but should always be considered on the basis of the presurgical evaluation and the intraoperative findings.

Submandibular Gland Ptosis

Prominent submandibular glands are seen in a subgroup of patients. Gland ptosis should be noted during the preoperative office evaluation. In these cases, a thoughtful preoperative discussion with the patient about his or her expectations and then limiting surgery appropriately may be best. This author does not favor either partial submandibular gland resection or intracapsular release and repositioning. The risk of complications (i.e., salivary gland drainage, hematoma, nerve damage, contour irregularities) may be greater than any cosmetic advantage. This explains why the surgical manipulation of the submandibular gland has not achieved general acceptance.

Direct Anterior Neck Skin Excision

In general, this author does not favor direct skin removal from the anterior neck with the use of Z-plasty, W-plasty, or other similar procedures. The resulting scars are frequently objectionable, although some surgeons favor these approaches for selected older men. It would be very difficult to justify such procedures for a young person, especially a

younger woman. If skin removal is required, a traditional face lift is more likely to result in patient satisfaction (i.e., less-visible scars and preferred neck rejuvenation).

Facial Aging and Rejuvenation: Treatment Pitfalls

Pitfalls of a "Soft-Tissue–Only Approach" to Facial Rejuvenation

When a middle-aged woman consults a cosmetic surgeon to discuss aging in the lower face and neck, she may typically ask about the following:

- A weak-appearing chin
- A double (soft-tissue) chin and excess neck fat
- Loose neck skin and a poor neck–jaw angle
- Deep nasolabial folds
- Heavy jowls
- Marionette lines and perioral lines, creases, or folds

The surgeon may discuss with the patient non-surgical and surgical options that include the following:

- The injection of non-autogenous "fillers"
- The injection of autogenous fat grafts
- Skin care and resurfacing techniques
- Anterior neck surgical procedures
- A spectrum of face-lift surgical options

If baseline maxillomandibular skeletal disproportions are pronounced, the surgeon is likely to suggest the following:

- The injection of fillers and fat grafts to augment the recognized skeletal deficiencies
- The placement of "hard" implants (e.g., Silastic, porous polyethylene) to augment the recognized skeletally deficient regions (i.e., the chin; the angles of the mandible; and the perinasal, infraorbital, and zygomatic regions)

The surgeon may neglect to consider patient-specific *smile aesthetics* or *jaw dysmorphology* when discussing treatment options. Interestingly, the patient is not likely to intuitively equate these aspects. In addition, neither the patient nor the surgeon is likely to consider the *potential cause-and-effect relationship between skeletal dysmorphology and baseline breathing difficulties (i.e., maxillomandibular deficiency and obstructive sleep apnea;* see Chapter 26).

The reasons why a surgeon may not fully consider the interrelationships of soft-tissue facial aging and jaw dysmorphology; baseline breathing difficulty and jaw dysmorphology; and smile aesthetics and dental disharmony may relate to a tendency for clinicians to suggest treatment options that they are most familiar with and personally able to perform.

A preferred approach is to educate the patient about pertinent aspects that may go beyond the original chief complaint and the surgeon's immediate expertise.[43,58,78,79,86-92] To best ensure a successful outcome and a satisfied patient, a comprehensive discussion of pertinent findings should precede any compromised treatment delivered (Figs. 40-12 and 40-13).

When a clinician attempts to achieve facial rejuvenation by overcompensating with a soft-tissue–only approach (i.e., the excessive injection of fillers or overtightening of the facial soft tissues) without addressing baseline skeletal deformities and disproportions, a suboptimal result is more likely.

A fundamental principle is that both smile aesthetics and optimal neck rejuvenation are highly dependent on acceptable dental harmony and reasonable maxillofacial skeletal proportions, respectively.

In addition, overlooking baseline upper airway obstruction as a result of maxillomandibular deficiency is not ideal for two reasons. First, the clinician has the obligation to inform patients of their health needs. Second, if a surgical procedure is undertaken (i.e., face lifting under anesthesia), then any baseline airway compromise (e.g., obstructive sleep apnea) may increase perioperative risk.

Pitfalls of a "Dental-Only Approach" to Facial Rejuvenation

When a middle-aged woman consults a restorative dentist or an orthodontist with a chief complaint of an unattractive smile, it is tempting for the clinician to only consider the alignment, shape, and color of the teeth (see Fig. 40-3). If the dentition and occlusion cannot be adequately improved through a combination of restorative dentistry and orthodontic mechanics, a dentofacial deformity should be suspected. The consulted orthognathic surgeon may then be tempted to limit the discussion to the "simplest way" to correct the occlusion (i.e., one-jaw surgery) without fully considering skeletal dysmorphology, facial aesthetics, or any baseline upper airway issues (e.g., chronic nasal obstruction, obstructive sleep apnea). For example, the individual with a long face Class II anterior open-bite growth pattern may arrive to the surgeon with a request from the orthodontist to "close the bite." It may be possible to achieve an acceptable occlusion with surgically assisted rapid palatal expansion and further orthodontic alignment. Doing so may resolve the open bite, but it is unlikely to address the following:

- Gummy smile
- Lip incompetence
- Chronic nasal obstruction
- Baseline obstructive sleep apnea
- Appearance of a "big" nose, "flat" cheekbones, and "weak" chin
- Negative-vector globe/eyelid relationship

Full disclosure to the individual regarding the limitations of an isolated dental or occlusion-only approach and the potential advantages of selecting a more comprehensive reconstruction best ensures patient satisfaction.

Difficulty achieving an optimal outcome may also occur when the restorative dentist or the orthodontist has overoptimistic expectations of what can be achieved through limited "surgical cosmetic" procedures. For example, the dental team may incorrectly assume that, if they are able to improve the occlusion in an individual with mandibular deficiency, then a chin implant will resolve the aesthetic concerns (see Fig. 38-1). It should be within the collaborative skill set of the treating orthodontist and the consulting orthognathic surgeon to broadly evaluate the patient's dental rehabilitative, jaw reconstruction, and rejuvenation needs.

Pitfalls of a Segmental Soft-Tissue Approach to Facial Rejuvenation

At times, a surgeon will be asked to perform a limited "segmental" soft-tissue approach to an individual's facial aging. For example, the patient shown in Fig. 40-14 presents with

• **Figure 40-12** A woman in her 50s requested evaluation for a "weak chin" and unfavorable neck aesthetics. Since her teenage years, she was known to have significant mandibular deficiency and a degree of maxillary hypoplasia. She underwent orthodontic treatment only and has a stable occlusion. Maxillary and mandibular osteotomies with advancement would best restore Euclidean proportions, open the airway, and rejuvenate the face (see Chapters 23 and 25). She was not prepared to undergo further orthodontics or an orthognathic approach. A compromised treatment plan was agreed to that included osseous genioplasty (vertical lengthening and minimal horizontal advancement) with interpositional bloc hydroxyapatite grafting and an anterior approach to the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication). **A,** Frontal views before and after surgery. **B,** Oblique facial views before and after surgery.

• **Figure 40-12, cont'd C,** Profile views before and after reconstruction. **D,** Lateral cephalometric radiographs before and after reconstruction.

a degree of brow ptosis; asymmetric upper eyelid ptosis and hooding; lower eyelid fat protrusion; deep nasolabial and perioral folds; heavy jowls; and neck submental soft-tissue fullness that involves all of the layers (i.e., skin, platysma, and fat). There is also notable surface-layer skin aging and a degree of maxillomandibular deficiency.

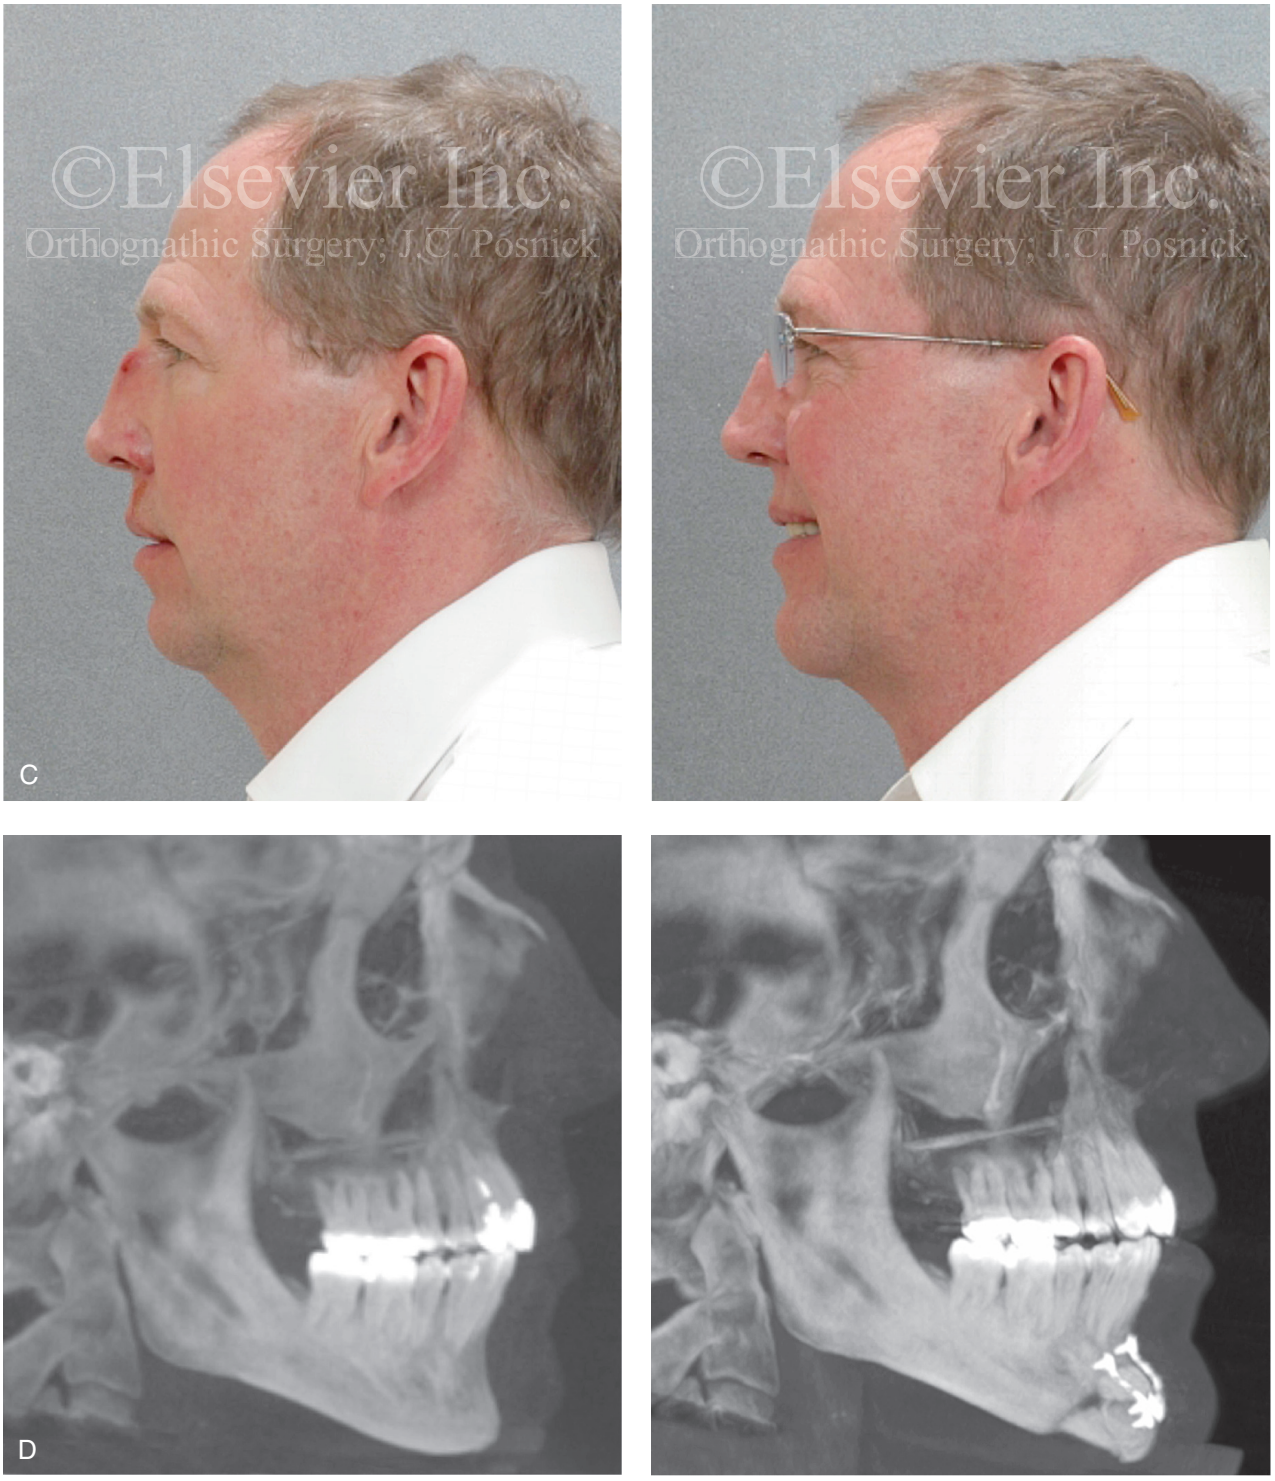
The patient requested the management of only the soft-tissue aging issues in the neck and jowls. This limited goal was reasonably achieved with a face lift. However, residual aging affecting the upper face (i.e., the brow and eyelids) was not addressed, which explains the suboptimal result. The surgeon's agreeing to a compromised soft-tissue "segmental" rejuvenation approach should be with full disclosure to the patient to avoid any misunderstandings.

Conclusions

The layers of the face include the skin, the underlying soft tissues and the skeletal structural support system (i.e., the bone, the cartilage, and the teeth). The soft tissues of the face will naturally descend with age. These and other soft-tissue changes occur throughout the face and neck and will alter the natural youthful facial curvatures. Nevertheless, an unavoidable fact is that the visual appearance of aging in the neck is greatly influenced by the baseline maxillomandibular skeletal framework. Consideration should be given to reconstructing the jaws toward Euclidian proportions, when feasible, before extensive soft-tissue procedures are undertaken.

Standard soft-tissue neck rejuvenation procedures remain an important part of the surgeon's armamentarium and include cervical skin flap undermining and elevation; defatting below the mandible platysmaplasty; and traditional face lifting. The clinician's knowledge of common patterns of dentofacial skeletal dysmorphology and their expected negative effects on soft-tissue aging—in combination with up-to-date methods for reconstruction and rejuvenation—best ensures optimal patient care.

• **Figure 40-13** A man in his early 50s was in a bicycle accident and sustained a displaced nasal fracture and an upper lip laceration. During the consultation, he also discussed a lifelong concern about a weak profile and, with age, the progressive laxity of the neck soft tissues. A lateral cephalometric and Panorex radiograph confirmed the nasal fracture and the microgenia. The patient had a stable occlusion without excess overjet. The nasal fracture required closed reduction with packing, and the upper lip laceration was approximated with suture for primary closure. The patient also underwent an osseous genioplasty (vertical lengthening and horizontal advancement) with interpositional bloc hydroxyapatite grafting and an anterior approach to the soft tissues of the neck (cervical flap elevation, neck defatting, and vertical platysma muscle plication). He is shown before and 3 months after the procedures. **A,** Frontal views before and after surgery. **B,** Oblique facial views before and after surgery.



• **Figure 40-13, cont'd** **C,** Profile views before and after surgery. **D,** Lateral cephalometric radiographs before and after surgery.

• **Figure 40-14** A woman in her mid 50s arrived with a request for neck rejuvenation. Over the years, excess loose skin had developed around her neck. She had a mild degree of maxillomandibular deficiency that was characterized as diminished lower anterior facial height and limited horizontal projection. The surface layer of the skin was thin with spotty pigmentation and wrinkling. She also had significant brow and upper eyelid ptosis. She did not wish to undergo an orthognathic correction, and she refused rejuvenation of the brow and eyelids at this time. She requested a segmental soft-tissue surgical approach that was restricted to the neck and jowls. Her face lift was carried out as described in the legend for Fig. 40-5. The aesthetic results are limited as a result of the inability to manage upper-face soft-tissue aging and the maxillomandibular skeletal deficiency. **A,** Frontal views before and after surgery. **B,** Oblique facial views before and after surgery. **C,** Profile views before and after surgery.

Patient Education Materials

Neck Liposuction Surgery

Liposuction and direct excision are surgical techniques that are used for the removal of excess fatty tissue. They are appropriate procedures to use in the neck region, and they may be carried out through a small incision below the chin. The presence of firm, elastic skin in the neck region will result in the most favorable contours after fat removal.

During liposuction, a cannula (i.e., a thin tube with an opening near the end) is inserted, and the surgeon moves it back and forth under the skin while high-pressure suction removes the unwanted fat. Fat removal in the neck can be done alone or in conjunction with other procedures (e.g., platysma muscle tightening, genioplasty, jaw-straightening surgery).

After the neck liposuction procedure, a tight-fitting dressing is applied to limit swelling and to help your skin conform smoothly to the new shape of your underlying tissue. Within 1 week, the stitches are removed. Depending on whether other procedures were carried out simultaneously, most people are then ready to go back to their work environment.

INSTRUCTIONS FOR NECK LIPOSUCTION SURGERY

The purpose of these instructions is to help you to prepare for and then recover from your operation with as little discomfort and inconvenience as possible.

Preoperative Instructions

1. Do not take any aspirin, aspirin-containing products, or aspirin-like products for at least 2 weeks before and 2 weeks after surgery. Aspirin and aspirin-like products tend to increase bleeding during surgery and bruising postoperatively.
2. You should not smoke for at least 2 weeks before surgery and 2 weeks afterward. Smoking jeopardizes wound healing, it may result in lung congestion, and it will hinder optimal results.
3. Starting at least 2 days before surgery, we request that you shower and shampoo your hair at least once per day. The morning of surgery, shower and shampoo your hair again.
4. Do not eat or drink anything after midnight the night before surgery, not even a sip of water.
5. Be sure to make arrangements for someone to accompany you home after surgery, because you will not be allowed to drive.
6. We will give you a prescription for pain control and another for antibiotics. You may wish to fill them before the date of surgery.

Postoperative Instructions

1. Applying a cold compress to the anterior neck region during the initial 36 hours after surgery will reduce swelling and discomfort.
2. Keep your head and upper back elevated when resting and sleeping for the first week after surgery.
3. You may eat whatever you wish, but start out slowly, because the anesthesia may leave your stomach unsettled for several hours.
4. Maintaining some compression in the neck region for at least 1 week after surgery may be helpful to minimize swelling and for the healing of the skin to the deeper structures of the neck. This is achieved with a specialized neck pressure garment that is applied during surgery. Your surgeon will also provide you with specific instructions about the neck dressing.
5. For men, shaving with an electric razor maybe preferred until you become comfortable with the changes in the sensation of the neck skin region.
6. Get lots of rest and perform minimal physical activity during the first week after surgery. You may then gradually increase your activity back to normal by 4 to 6 weeks after your operation as per instructions from your surgeon.
7. Palpable small lumps and a tight feeling in the neck just below the chin are common findings. These will gradually improve during the final phase of healing.
8. Call the office for an appointment to see your surgeon on the date specified at the time of discharge.
9. If there are concerns at any time, contact your surgeon's office. After hours, the answering machine message will advise you about how to proceed.

Jeffrey C. Posnick, DMD, MD
Director, Posnick Center for Facial Plastic Surgery

Consent for Neck Liposuction Surgery

_____ **INSTRUCTIONS**

Initial here This is a document that has been prepared by your surgeon to help educate and inform you about your suction-assisted lipectomy (liposuction) surgery and its risks as well as alternative treatment options. It is important that you read this information carefully and completely. Please initial each section on each page to indicate that you have read and understand it. When all of your questions are answered, please also sign the consent for surgery on the last page as proposed by your surgeon.

_____ **INTRODUCTION**

Initial here Liposuction and direct excision are surgical techniques that are used for the removal of excess fatty tissue. They are appropriate procedures to use in the neck region, and they are carried out through a small incision below the chin. The presence of firm, elastic skin will result in the most favorable neck contour after fat removal. During liposuction, a cannula (i.e., a thin tube with an opening near the end) is inserted, and the surgeon moves it back and forth under the skin while high-pressure suction removes the unwanted fat.

Fat removal in the neck can be done alone or in conjunction with other procedures (e.g., platysma muscle tightening, genioplasty, jaw-straightening surgery). After the liposuction procedure, a tight-fitting dressing is usually applied to the neck to limit swelling and to help the skin conform smoothly to the new shape of the underlying tissue. Within 1 week, the stitches are removed. Depending on whether other procedures were carried out simultaneously, most people are then ready to return to their work environment.

_____ **ALTERNATIVE TREATMENT**

Initial here Alternative forms of management include the decision to not treat the fatty deposits with surgery. Diet and exercise regimens may be of benefit for the overall reduction of excess body fat. In some patients, the removal of excess skin in the neck with the use of a more extensive neck lift or face lift technique may be required in addition to liposuction. Risks and potential complications are also associated with these and other alternative forms of treatment.

_____ **RISKS OF NECK LIPOSUCTION SURGERY**

Initial here Every surgical procedure involves a certain amount of risk. An individual's choice to undergo a neck liposuction procedure is based on the comparison of the risk to the potential benefit. Although the majority of patients do not experience the complications described below, you should discuss each of them with your surgeon.

_____ **PATIENT SELECTION**

Initial here Individuals with poor skin tone, medical problems, obesity, or unrealistic expectations may not be candidates for neck liposuction.

_____ **BLEEDING**

Initial here It is possible, although unusual, to have a significant bleeding episode during or after neck liposuction. If postoperative bleeding does occur, urgent treatment to drain accumulated blood or to control ongoing bleeding may be required. Do not take any aspirin or aspirin-like medications for 2 weeks before surgery, because this may increase the risk of bleeding. Individuals with poorly controlled hypertension are also at risk.

_____ **INFECTION**

Initial here Infection is not common after neck liposuction surgery. If an infection does occur, treatment that includes a change in antibiotics or additional surgery may be necessary.

_____ **SKIN SCARRING**

Initial here Although good wound healing after neck liposuction is expected, abnormal scarring may occur within the skin and the deeper tissues. Additional treatments, including surgery, may be helpful to treat abnormal scarring.

_____ **CHANGES IN SKIN SENSATION**

Initial here A decrease in skin sensation after neck liposuction may occur. This usually resolves over a period of time.

_____ **SKIN DISCOLORATION AND SWELLING**

Initial here Skin discoloration and swelling normally occur after neck liposuction. In rare situations, swelling and skin discoloration may persist.

_____ **SKIN CONTOUR IRREGULARITIES**

Initial here Contour irregularities, palpable wrinkling, and depressions in the skin may occur after liposuction. Additional treatments, including surgery, may be helpful to manage skin contour irregularities.

_____ **NECK ASYMMETRY**

Initial here It may not be possible to achieve a symmetric appearance with neck liposuction procedures. Factors such as skin or muscle tone and bony prominences also contribute to the noticeable asymmetry of the facial features.

_____ **LONG-TERM EFFECTS**

Initial here Subsequent alterations in neck contour may occur as a result of aging, weight loss or gain, or other circumstances not related to liposuction.

_____ **SURGICAL ANESTHESIA**

Initial here Both local and general anesthesia involve risk. Complications are possible with all forms of anesthesia and sedation.

_____ **ALLERGIC REACTION**

Initial here Local allergies to tape, suture materials, or topical preparations have been reported. Systemic reactions, which are more serious, may occur in response to drugs that are used during surgery or prescription medications taken afterward.

_____ **HEALTH INSURANCE**

Initial here Most health insurance companies exclude coverage for cosmetic procedures such as liposuction or for any related complications that may occur. Please carefully review your health insurance subscriber information.

_____ **ADDITIONAL SURGERIES THAT MAY BE NECESSARY**

Initial here There are many variable conditions in addition to risks and potential surgical complications that may influence the long-term results of neck liposuction. Although complications occur infrequently, the risks cited are those that are particularly associated with neck liposuction. The practice of medicine and surgery is not an exact science. Although good results are expected, there is no guarantee or warranty expressed or implied with regard to the results that may be obtained.

Continued

_____ **FINANCIAL RESPONSIBILITIES**

Initial here The cost of surgery involves several charges for the services provided, including the fees charged by your surgeon (i.e., surgeon's fees); the cost of surgical supplies and the use of the operating room (i.e., facility/hospital charges); and the costs associated with anesthesia (i.e., anesthesiologist's fees). Depending on whether the cost of surgery is covered by your medical insurance plan, you will be responsible for necessary copayments, deductibles, and all other charges that are not covered. Additional costs may occur should complications develop from the surgery. Any secondary surgeries and all charges involved with additional procedures (i.e., surgeon's fees, facility/hospital charges, anesthesiologist's fees) would also be your responsibility.

_____ **DISCLAIMER**

Initial here Informed-consent documents are used to communicate information about the proposed surgical treatment as well as to disclose information about risks and alternative forms of treatment. The informed-consent process attempts to define principles of risk disclosure that should generally meet the needs of most patients in most circumstances.

Informed-consent documents should not be considered all-inclusive with regard to defining other methods of treatment and potential risks encountered. Your surgeon will provide you with additional written and verbal information that is based on all of the facts of your particular case and the state of medical knowledge.

Informed-consent documents are not intended to define or serve as the standard of medical care. Standards of medical care are determined on the basis of all of the facts involved in an individual case and are subject to change as scientific knowledge and technology advance and as practice patterns evolve.

CONSENT FOR NECK LIPOSUCTION SURGERY

1. I hereby authorize my surgeon, _____, and such assistants as may be selected by my surgeon to perform the following procedure:
   - Neck region liposuction.
2. I have received, read, and understand the following information sheets:
   - Neck Liposuction Surgery
   - Consent for Neck Liposuction Surgery
3. I recognize that, during the course of the operation and the administration of anesthesia, unforeseen conditions may necessitate different procedures than those stated above. I therefore authorize my surgeon, _____, and my surgeon's assistants or designees to perform such other procedures that are in the exercise of professional judgment necessary and desirable. The authority granted under this paragraph shall include all conditions that require treatment and that are not known to my surgeon at the time that the procedure is begun.
4. I consent to the administration of such anesthetics as are considered necessary or advisable. I understand that all forms of anesthesia involve risk and the possibility of complications, injury, and even death.
5. I acknowledge that no guarantee has been given by anyone with regard to the results that may be obtained from this procedure.
6. I consent to the photographing of me (head and neck region) before, during, and after surgery. These photographs may be used by my surgeon for medical, scientific, or educational purposes now and in the future.
7. For the purposes of advancing medical education, I consent to the admittance of observers into the operating room.
8. I consent to the disposal of any body tissues or medical devices that may be removed.
9. **THE FOLLOWING INFORMATION HAS BEEN EXPLAINED TO ME IN A WAY THAT I UNDERSTAND:**
   - **THE PREVIOUSLY DESCRIBED PROCEDURES TO BE UNDERTAKEN**
   - **ALTERNATIVE PROCEDURES AND METHODS OF TREATMENT THAT I HAVE DECIDED AGAINST**
   - **THE SPECIFIC RISKS AND POTENTIAL COMPLICATIONS OF THE PROCEDURES THAT I PLAN TO UNDERGO**

I CONSENT TO THE PROCEDURES AND THE ABOVE LISTED ITEMS (1 THROUGH 9). I AM SATISFIED WITH THE EXPLANATION GIVEN TO ME.

Anterior Neck Lift Surgery

Liposuction and direct excision are surgical techniques that are used for the removal of excess fatty tissue. They are appropriate procedures to use in the neck region, and they may be carried out through a small incision below the chin. During liposuction, a cannula (i.e., a thin tube with an opening near the end) is inserted, and the surgeon moves it back and forth under the skin while high-pressure suction removes the unwanted fat.

Depending on the quality of your skin and underlying muscles, *an anterior neck lift* procedure may be beneficial. An anterior neck lift is carried out through the same small incision as liposuction. By elevating the neck skin away from the deeper structures, there is a tendency for the skin to tighten in a positive way during the healing process. If skin laxity is extensive, then a more traditional face lift procedure (i.e., with incisions in front of and behind the ears) would be beneficial to directly remove the excess skin.

Just deep to the skin of the neck, there is a thin, sheet-like muscle layer (i.e., the platysma muscles) that may also become lax and benefit from surgical tightening. Platysma muscle tightening (i.e. platysmaplasty) can be performed in conjunction with cervical (neck) skin undermining as described to further improve the shape and contour of the neck.

After the *anterior neck lift* procedures, (i.e., cervical flap undermining, fat removal, and platysmaplasty), a tight-fitting dressing is usually applied to limit swelling and to help the skin conform more smoothly to the new shape of the underlying tissue. Within 1 week, the stitches are removed. Depending on whether other procedures are carried out simultaneously, most people then return back to their work environment.

INSTRUCTIONS FOR ANTERIOR NECK LIFT SURGERY

The purpose of these instructions is to help you to prepare for and then recover from your operation with as little discomfort and inconvenience as possible.

Preoperative Instructions

1. Do not take any aspirin, aspirin-containing products, or aspirin-like products for at least 2 weeks before and 2 weeks after surgery. Aspirin and aspirin-like products tend to increase bleeding during surgery and bruising postoperatively.
2. You should not smoke for at least 2 weeks before surgery and 2 weeks afterward. Smoking jeopardizes wound healing, it may result in lung congestion, and it will hinder optimal results.
3. Starting at least 2 days before surgery, we request that you shower and shampoo your hair at least once per day. The morning of surgery, shower and shampoo your hair again.
4. Do not eat or drink anything after midnight the night before surgery, not even a sip of water.
5. Be sure to make arrangements for someone to accompany you home after surgery, because you will not be allowed to drive.
6. We will give you a prescription for pain control and another for antibiotics. You may wish to fill them before the date of surgery.

Continued

Postoperative Instructions

1. Applying a cold compress to the anterior neck region during the initial 36 hours after surgery will reduce swelling and discomfort.
2. Keep your head and upper back elevated when resting and sleeping for the first week after surgery.
3. You may eat whatever you wish, but start out slowly, because the anesthesia may leave your stomach unsettled for several hours.
4. Maintaining some compression in the neck region after surgery may be helpful to minimize and reduce swelling and for the healing of the skin to the deeper structures of the neck. Each situation is unique, and your surgeon will advise you with regard to this matter.
5. For men, shaving with an electric razor may be preferred until you become comfortable with the changes in sensation in the neck skin region.
6. Get lots of rest and perform only minimal physical activity during the first week after surgery. You may then gradually increase your activity back to normal by 4 to 6 weeks after your operation as per instructions from your surgeon.
7. Palpable small lumps and a tight feeling in the neck are common findings. These will gradually improve during the final phase of healing.
8. Call the office for an appointment to see your surgeon on the date specified at the time of discharge.
9. If there are concerns at any time, contact your surgeon's office. After hours, the answering machine message will advise you about how to proceed.

Consent for Anterior Neck Lift Surgery

_____ Initial here

INSTRUCTIONS

This is a document that has been prepared by your surgeon to help educate and inform you about your anterior neck lift surgery and its risks as well as alternative treatment options. It is important that you read this document carefully and completely. Please initial each section to indicate that you have read and understand it. In addition, please sign the consent for surgery on the last page as proposed by your surgeon.

_____ Initial here

INTRODUCTION

Liposuction is a surgical technique to remove excess fatty tissue. It is an appropriate procedure to use in the neck region, and it is carried out through a small incision below the chin. During liposuction, a cannula (i.e., a thin tube with an opening near the end) is inserted, and the surgeon moves it back and forth under the skin while high-pressure suction removes the unwanted fat.

Depending on the quality of your skin and underlying muscles an anterior neck lift procedure may be beneficial. The anterior neck lift is carried out through the same small incision just below the chin. By elevating the neck skin away from the deeper structures, there is a tendency for the skin to tighten in a positive way. If skin laxity is extensive, then a more traditional face lift procedure may be required to directly remove the excess skin.

Just deep to the skin of the neck, there is a thin, sheet-like muscle layer (i.e., the platysma muscles) that may also become lax and benefit from surgical tightening. Platysma muscle tightening (platysmaplasty) can be done in conjunction with cervical (neck) skin undermining and fat removal as described to further improve the shape and contour of the neck.

_____ Initial here

ALTERNATIVE TREATMENT

Alternative forms of management may include the decision to not treat the neck soft-tissue concerns with surgery at all. Diet and exercise regimens may be of benefit for the overall reduction of excess body fat. The direct removal of excess skin (i.e., a traditional face lift) may be advantageous in addition to the fat removal and skin redraping procedures (i.e., the anterior neck lift) that you are currently planning to undergo. Risks and potential complications are also associated with these and other alternative forms of treatment.

_____ **RISKS OF NECK REJUVENATION PROCEDURES**

Initial here Every surgical procedure involves a certain amount of risk. It is important that you understand the risks involved with the anterior neck rejuvenation procedure that is planned for you. An individual's choice to undergo a surgical procedure is based on the comparison of the risk to the potential benefit. Although the majority of patients do not experience these complications, you should discuss each of them with your surgeon.

_____ **PATIENT SELECTION**

Initial here Individuals with poor skin tone, medical problems, obesity, or unrealistic expectations may not be candidates for a neck rejuvenation procedure.

_____ **BLEEDING**

Initial here It is possible, although not usual, to have a significant bleeding episode during or after surgery. If postoperative bleeding occurs, it might require urgent treatment to drain the accumulated blood or to control any ongoing bleeding. Do not take any aspirin or anti-inflammatory medications for 2 weeks before surgery, because this may increase the risk of bleeding. Individuals with poorly controlled hypertension are also at risk for postsurgical bleeding.

_____ **INFECTION**

Initial here Infection is not usual after this type of surgery, and you will be given perioperative antibiotics to limit this risk. If an infection occurs, a change in antibiotics and additional surgery may be necessary.

_____ **SKIN SCARRING**

Initial here Although good wound healing after neck rejuvenation is expected, abnormal scars may occur within the skin and the deeper tissues. Additional treatments, including surgery, may be beneficial to treat abnormal scarring.

_____ **CHANGE IN SKIN SENSATION AND LIP FUNCTION**

Initial here A decrease in skin sensation after neck rejuvenation may occur. Diminished neck skin sensation may not totally resolve.

_____ **SKIN DISCOLORATION AND SWELLING**

Initial here Skin discoloration and swelling normally occur after neck rejuvenation. In rare situations, swelling and skin discoloration may persist.

_____ **SKIN CONTOUR IRREGULARITIES**

Initial here Contour irregularities, or palpable wrinkling may occur in the skin after neck rejuvenation. Additional treatments, including surgery, may be beneficial to manage skin contour irregularities.

_____ **NECK ASYMMETRY**

Initial here It may not be possible to achieve a symmetric appearance with neck rejuvenation procedures. Factors such as skin or muscle tone and bony prominences may also contribute to a noticeable asymmetries.

_____ **SEROMA**

Initial here Fluid accumulation infrequently occurs in areas where neck rejuvenation has been performed. Additional treatments or surgery to drain accumulations of fluid may be necessary.

Continued

_____ **LONG-TERM EFFECTS**

Initial here Subsequent alterations in facial contour may occur as a result of aging, weight loss or gain, or other circumstances not related to the specific procedures that have been carried out.

_____ **SURGICAL ANESTHESIA**

Initial here Both local and general anesthesia involve risk. Complications are possible with all forms of anesthesia and sedation.

_____ **ALLERGIC REACTION**

Initial here Local allergies to tape, suture materials, or topical preparations may also occur. Systemic reactions, which are more serious, may occur in response to drugs that are used during surgery or prescription medication taken afterward.

_____ **HEALTH INSURANCE**

Initial here Most health insurance companies exclude coverage for cosmetic operations such as neck rejuvenation or any related complications that may occur. Please carefully review your health insurance subscriber information.

_____ **ADDITIONAL SURGERIES THAT MAY BE NECESSARY**

Initial here There are many variable conditions in addition to risks and complications that may influence the long-term results of a neck rejuvenation procedure. Although complications occur infrequently, the risks cited are those that are particularly associated with a neck rejuvenation procedure. Other complications and risks can occur but are even more uncommon. If complications do occur, additional surgeries or other treatments may be necessary. The practice of medicine and surgery is not an exact science. Although favorable results are expected, there is no guarantee or warranty expressed or implied with regard to the results that may be obtained.

_____ **FINANCIAL RESPONSIBILITIES**

Initial here The cost of surgery involves several charges for the services provided, including the fees charged by your surgeon (i.e., surgeon's fees); the cost of surgical supplies and the use of the operating room (i.e., facility/hospital charges); and the costs associated with anesthesia (i.e., anesthesiologist's fees). Depending on whether the cost of surgery is covered by your medical insurance plan, you will be responsible for necessary copayments, deductibles, and all other charges that are not covered. Additional costs may occur should complications develop from the surgery. Any secondary surgeries and all charges involved with additional procedures (i.e., surgeon's fees, facility/hospital charges, anesthesiologist's fees) would also be your responsibility.

_____ **DISCLAIMER**

Initial here Informed-consent documents are used to communicate information about the proposed treatment of a disease or condition as well as to disclose information about risks and alternative forms of treatment. The informed-consent process attempts to define principles of risk disclosure that should generally meet the needs of most patients in most circumstances.

However, informed-consent documents should not be considered all-inclusive with regard to defining other methods of care and potential risks encountered. Your surgeon may provide you with additional written and verbal information that is based on all of the facts of your particular case and the state of medical knowledge.

Informed-consent documents are not intended to define or serve as the standard of medical care. Standards of medical care are determined on the basis of all of the facts involved in an individual case and are subject to change as scientific knowledge and technology advance and as practice patterns evolve.

CONSENT FOR ANTERIOR NECK LIFT SURGERY

1. I hereby authorize my surgeon, _____, and such assistants as may be selected by my surgeon to perform the following procedure: neck rejuvenation surgery that includes the removal of fat, cervical (neck skin) undermining, and platysma muscle plication.
2. I have received, read, and understand the following information sheets:
   - Anterior Neck Lift Surgery
   - Consent for Anterior Neck Lift Surgery
3. I recognize that, during the course of the operation and the administration of anesthesia, unforeseen conditions may necessitate different procedures than those stated above. I therefore authorize my surgeon, _____, and my surgeon's assistants or designees to perform such other procedures that are in the exercise of professional judgment necessary and desirable. The authority granted under this paragraph shall include all conditions that require treatment and that are not known to my surgeon at the time that the procedure is begun.
4. I consent to the administration of such anesthetics as are considered necessary or advisable. I understand that all forms of anesthesia involve risk and the possibility of complications, injury, and even death.
5. I acknowledge that no guarantee has been given by anyone with regard to the results that may be obtained from this procedure.
6. I consent to the photographing of me (head and neck region) before, during, and after surgery. These photographs may be used by my surgeon for medical, scientific, or educational purposes now and in the future.
7. For the purposes of advancing medical education, I consent to the admittance of observers into the operating room.
8. I consent to the disposal of any body tissues or medical devices that may be removed.
9. **THE FOLLOWING INFORMATION HAS BEEN EXPLAINED TO ME IN A WAY THAT I UNDERSTAND:**

jaw deformities and, 1356-1357
orthodontic approaches, 1356-1357
orthognathic approaches, 1299f-1305f, 1307f-1312f, 1317f-1354f, 1357-1359
controversies of, 1363-1365
distraction osteogenesis (DO) and, 1365
evolution of, 1357-1358
initial surgical healing, 1360
Le Fort I osteotomies, modified, 1358-1359
Le Fort I osteotomies, standard, 1358
Le Fort I osteotomies, two-segment, 1358-1359

Unilateral cleft lip/palate (UCLP) *(Continued)*
maxillary reconstruction, staging of, 1363-1364
mixed dentition and, 1364
pitfalls of, 1359-1361
skeletal relapse and, 1364-1365
skeletal stability and, 1362-1363
studies of, 1361-1363
unresolved issues of, 1363-1365
velopharyngeal (VP) function and, 1364
presurgical assessments, 1357
treatment protocols, 1299f-1305f, 1304-1306, 1307f-1312f, 1317f-1354f
Unilateral condylar hyperactivity, 860-861
Unilateral maxillary crossbite, 271-272
Unilateral oto-mandibular dysostosis, 1095. *See also* Hemifacial microsomia (HFM).
Unstable *vs*. unreliable centric relation (CR), 427. *See also* Centric relation (CR).
Unvoiced sounds, 235
Upper airway, 995, 995f
length (UAL), 999
resistance syndrome (UARS), 994
surgery, 1010-1045
Upper face reference
maxillary cant, 361-362
maxillary dental midline, 361
maxillary incisor crown vertical position, 362-363
maxillary incisor crown horizontal position, 363-367
Upper helix, failure *vs*. relapse, 1730-1731
Upper midface deformities, 1232
UPPP. *See* Uvulopalatopharyngoplasty (UPPP).
U.S. National Health and Nutrition Examination Survey III (NHANES III), 64
Uvulopalatopharyngoplasty (UPPP), 1010-1045

van der Wound syndrome, 77-91, 84f
Vascular complex malformations, 1277-1288. *See also* Complex malformations.
arteriovenous, 1280-1282, 1286f-1287f
capillary, 1288
characteristics of, 1277, 1280f-1287f
complications of, 1277
historical perspectives of, 1277
lymphatic, 1277-1279, 1282f-1283f
venous, 1279-1280
Vascular thrombosis, 180
VCFS. *See* Velocardiofacial syndrome (VCFS).
Vector-controlled forces, 137
Vectored force, 406
Velocardiofacial syndrome (VCFS), 1288. *See also* Complex malformations.
characteristics of, 1288
pathophysiology of, 1288
prevalence of, 1288
reconstruction in, 1288
Velopharyngeal (VP) dysfunction, 1428, 1443, 1444f-1445f
Velopharyngeal insufficiency (VPI), 254-259, 255f-258f
Ventilation, face-mask, 319
Vertical dimensions, 64
Vertical discrepancy, chin, 1565f-1571f, 1571-1572, 1573f-1593f. *See also* Chin.
Vertical maxillary excess patterns, 758-806. *See also* Long face patterns.
clinical characteristics of, 759
complications of, 802
definitive reconstruction for, 761-801
dental findings of, 759
diagnostic criteria for, 758
etiology of, 759-760
functional aspects of, 758-759
growth modification, preadolescent patients, 760
informed consent considerations, 802
orthodontic camouflage approach to, 760
orthodontic molar intrusion approach to, 760-761
patient education for, 802
postsurgical malocclusion, 802-803
postsurgical orthodontic maintenance, 802
prevalence of, 758, 803
radiographic findings of, 759
surgical planning for, 801-802
Virenque, Maurice, 53-55
Vision restoration, 12, 15f
Visual distortion speech errors, 237-240
Visual examinations, direct, 408
Vitamin D, 75
Vitamin D_3, 142-143
